magnetic compass, it is clear that the Chinese were using it for geomancy and divination by the first century A.D. Their earliest use of the compass in navigation is unclear; the first datable references occur in about the eleventh century, but it is certain that Chinese mariners used compasses many years earlier. As in Europe, Chinese physicists used both “wet” and “dry” compasses; the former were made by floating magnetized needles in bowls of water whose rims were inscribed with directions, and the latter by carefully mounting the needle on an upright pivot.

What about the physics of surface phenomena? As in the West, its study was long delayed in China. Of course, knowledge of friction was very old among both cultures. Ancient Chinese, for example, knew how to use friction to make fires; and the friction of wheels was discussed in the *Han Zou Li*. By the Tang dynasty (A.D. 618–906), prince Li Kao studied the fit of smooth surfaces, and in the thirteenth century, Zhou Mi studied monomolecular films. And, during the Sung dynasty (A.D. 960–1279) Zhang Shi-Nan’s 1233 treatise, *Yu Huan Zhen Wen* (Things Seen and Heard on My Official Travels), discusses the ring-test to determine the quality of lacquer. The ring-test was a method of quality control for centuries; it was not until 1878 that it was applied to measuring surface tension by finding the force to break the surface.

In China as in Europe, heat and combustion were a comparatively late interest. Making heat and sparks by rubbing wood and striking flint were techniques known to the ancient Chinese, and medieval texts give priority to the Chinese in the invention of the match (Northern Qi, A.D. 577). Candles were known to the Mohists in the Warring States period, and lamps since ancient times. But by the early eighth century A.D., Chinese lampmakers had cleverly designed an oil-cooling water reservoir below the lamp to reduce evaporation. The use of natural gas for fuel goes back to the first few centuries B.C.E., and Chinese inventors applied this knowledge on an industrial scale.

Some knowledge of the practical principles of steam power may go back as far as the second

century B.C.E., based on a passage in the undated Daoist alchemical and technical recipe book, the *Huai Nan Wan Bi Shu* (Ten Thousand Infallible Arts of the Prince of Huai-Nan). Interest in spontaneous combustion is also very old, and is discussed in accounts of the third century A.D. Chinese physicists also looked at successive boiling phases of liquids (particularly water for tea).

On the theoretical side, Li Shizhen’s sixteenth century *Bencao Gangmu* (Great Pharmacopoeia) of 1596 attempts to classify types of fire. Fire is of two varieties, Yin and Yang, with many subdivisions; in general, it has *qi* (energy) but not *chi* (matter). Shizhen could not classify luminescent “fires” like fluorescence, phosphorescence, electro-luminescence, and piezo-luminescence.

Electro-luminescence was described by Chinese physicists of the third century A.D. The *Bo Wuzhi* (Record of the Investigation of Things), of approximately A.D. 290, describes sparks created by contact with charged objects, such as drawing combs through the hair. As for other electrostatic phenomena, the ability of amber to attract objects when rubbed was known very early. Amber was first described by first century A.D. philosopher ► [Wang Chong](#), and its properties were discussed in more detail around A.D. 500 by alchemist-physician Tao Hong Jing. But there was little progress in electrostatics until the eighteenth century. Meanwhile, piezo-luminescence, caused by rubbing certain types of crystals, was known in the Tang dynasty. Artificial phosphors may have been studied in the Sung period; the eleventh century *Xiangshan Yelu* (Rustic Notes from Xiang Shan) of monk Wen Rong explains the making of a phosphor from oyster shells. Some of these crystals and phosphors may have been imported overland from Arabic cultures, Needham argues; and if so, they may well have similarly influenced Indian physics on the way.

India

There is still much historical research to be done on the growth and development of science in India. Hindu scientists have been justly

celebrated for their early contributions to mathematics (including the Hindu-Arabic number system, the use of zero, trigonometry, series summation, algebraic operations, and so on) and astronomy (elaborate computational techniques to determine the positions of celestial objects), but until recently little has been written on their physics, which is both sophisticated and extensive.

Early Indian physics is concerned with the “doctrine of the five elements” (*pañcamahabhūtas*); that is, the interplay between the elements of earth, water, fire, air, and a nonmaterial substance (*pṛthvī, ap, tejas, vāyu and ākāśa*, respectively). Among the earliest treatises of the ṛgveda period (2000–1500 B.C.E.) we see the emergence of primeval water as the “first cause” of all other elements, rather like the simple cosmologies of ancient Greek scientists like Thales (ca. 624–545 B.C.E.) and Anaximander (ca. 611–575 B.C.E.).

The five element theory was later developed by the Vaiśeṣika School of about 700–600 B.C.E., which also began the study of atomism. The introduction of Buddhism and Jainism brought new inquiries into the problems of atomism, matter, and motion (ca. 600–200 B.C.E.); this was followed by the systematic formulation of atomic theories among Indian physicists between 200 B.C.E. and A.D. 400. Indian science made its greatest advances between the period A.D. 400 and 1200, especially among the Jaina and Buddhist schools, as well as the Nyāya-Vaiśeṣika commentators. These medieval Indian physicists refined atomic theory, and made detailed investigations into gravity, motion, and impetus.

Physicists first began to explain the natural world in terms of atomic theories after 700 B.C.E. For the Vaiśeṣika School, atoms were eternal or indestructible, indivisible, and infinitely small. These atoms (*pramāṇus*) had vibratory and rotational motions, along with inherent impulses to form binary molecules (*dvyāṇuka*). Various combinations of atoms made up all the diverse substances in our world. Interestingly enough, this theory explained chemical reactions by supposing that these

substances were broken up into their original atoms (the *pramāṇu* state) before they could be recombined to make a new material.

Physical and chemical change, meanwhile, was closely linked to the theory of heat. The first century A.D. philosopher Vātsyāyana argued that chemical change occurs as a result of either internal or external heat; moreover, during combustion, heat trapped inside the fuel in a latent form is released, allowing chemical reactions to proceed. The *Kīranāvali* of Udayana ultimately traced all forms of heat back to their source in the Sun.

Ancient Hindus believed that both heat and light were composed of streams of infinitely small particles radiating in all directions from sources like the sun. These particles move at inconceivably high speeds, and, when they strike molecules, break them down into smaller atoms, promoting chemical change. This theory was described in detail in the eleventh century A.D. *Nyāyamañjari* of Jayanta.

Other factors governing matter and physical change included gravity (*gurutva*), fluidity (*dravatna*), viscosity (*sigdha*), and elasticity (*sthitishāpaka*). For the Vaiśeṣika, gravity was seen as a causal factor resulting in the fall of bodies; it is not a force in the modern sense. Moreover, only earth and water possess it. The later Nyāya-Vaiśeṣika school of physicists (ca. 400–1200) add that gravity could be cancelled out by the effects of conjunction (a object supported on a stand) or impetus (an arrow flying through the air). They argued that gravity is eternal for primeval atoms, but temporary for compounds.

Fluidity was of two types, natural and incidental, with the former reserved to water, the latter to water, earth, and fire. Viscosity governs cohesion and smoothness, and is a property of water, preventing particles in it from dispersing. Elasticity is a quality of earthy substances.

How did Indian physicists handle the problem of matter in motion? The Vaiśeṣika held that matter was naturally static or stationary. It could be moved by some physical quality, like gravity in a falling body, but this motion would be temporary; and perpetual motion was impossible.

Interestingly enough, it seems that gravity was only required to set the falling object in motion. Once it had started moving, impetus is generated, which keeps it falling without any additional help from gravity.

The fifth century A.D. philosopher Praśastapāda made a detailed study of motion and impetus in his *Pradārtha dharma saṃgraha*, a revision of the much older *Vaiśeṣikasūtra*. He divided motion into five categories: *utkṣepaṇa*, *avakṣepaṇa*, *prasāraṇa*, *ākuñcana*, and *gamana*, or, respectively, lifting up, throwing down, expansion, contraction, and action (gyrations, evacuations, quivering, and the like). Motion can be caused, says Praśastapāda, by six things: gravity, fluidity, volitional effort, conjunction (such as impact or striking), impetus or unseen causes. His use of impetus (*vega*) is rather close to our modern momentum, and is illustrated by the examples of throwing a heavy shot or firing an arrow. When the shot is thrown, the first impelling push begins its motion; then the shot's internal impetus takes over, and maintains its motion. Once the impetus is exhausted, the shot falls back to the ground.

Praśastapāda also had a relatively modern conception of sound. He realized sound was produced by vibrations in air, and added that these vibrations travel "like a series of water-ripples... or a series of waves" to the ear.

Indian physicists had many contacts with Chinese developments in the East, but they were equally well connected to Arabic work in the West. The relations between Indian and Islamic science in the Medieval period has recently been the focus of much scholarly work (Needham, Chin, Filliozat, Sen).

Islam

Islamic physicists, mathematicians, and astronomers such as Ibn Sīnā, Ibn al-Haytham, ► [al-Bīrūnī](#) and ► [al-Kindī](#) have long been known to Western historians for their influences on scholastic science in the Medieval Latin West. Arabic scientists frequently criticized and extended the physics of Aristotle, Archimedes (ca. 287–212 B.C.E.), and

other ancient physicists and often provided the original roots for many physical ideas, such as force and momentum.

In mechanics and dynamics, Muslim physicists developed several important concepts. Ibn Sīnā or Avicenna (980–1037) invoked the idea of *mayl* (Latin *inclinatio*, or inclination) to explain projectile motion; this theory was further developed by al-Baghdādī before its transmission to the Latin West. Ibn Sīnā and Ibn al-Haytham developed the concept of momentum, and did pioneering research into the theory of gravity. Muslim philosophers knew that falling bodies accelerated independently of their mass, and that the attractive power between two objects increased as their masses got larger, but decreased with their separation.

Arabic physicists extensively studied the theory of weights, densities, buoyancy, and measures. They were familiar with the law of the lever and Archimedes' principle, and developed the balance as a scientific instrument to study topics such as specific weights. Thābit ibn Qurra (836–901) worked extensively on the law of the lever, and his ideas were later quite influential in the West. Meanwhile, al-Khāzinī's (fl. 1115–1130) celebrated *Kitāb mizān al-ḥikmah* (Book of the Balance of Wisdom) developed formulae for the specific and absolute weights of various alloys. Al-Khāzinī's work also discusses centers of gravity, hydrostatics, and other physical concepts.

Many Islamic scientists extended the theory of simple machines. Among these researchers were Baghdad's ► [Banū Mūsā](#), and the many Arabic scientists involved with the development of various mechanical gadgets, automata, trick devices, and other complex machines. This branch of physics, called '*ilm al-ḥiyal*', was developed by the Banū Mūsā, the school of Ibn Sīnā, Ibn al-Sā'ati, and many more. It reached its climax in the famous *Kitāb fī ma'rifat al-ḥiyal al-handasiyyah* (Book of Knowledge of Ingenious Mechanical Devices) of ► [al-Jazarī](#).

Among the most influential researches of Muslim physicists were their pioneering inquiries into light and optics, which virtually established this branch of physics as an organized discipline.

Al-Kindī's (fl. 790–866) early treatises introduced Euclidean optics to the Medieval Latin West. His theories of vision influenced Islamic writers for several centuries, including al-Fārābī (d. 950), al-Ṭūsī (1201–1274), and many more.

Opticians such as Ibn Sīnā and al-Bīrūnī (973–ca. 1050) studied particular problems like the speed of light from ancient sources, usually declaring it to be finite. Meanwhile, doctors like ► [al-Rāzī](#) or Rhazes (ca. 854–935) and ► [Ḥunayn ibn Ishāq](#) inquired into human eye physiology, making their own contributions to the theory of vision. However, the most significant figure in Muslim optics was the Egyptian physicist Ibn al-Haytham (ca. 965–1039), better known in the West as Alhazen.

Many historians consider Ibn al-Haytham to be the most important optician between Euclid and Johannes Kepler (1571–1630). Historian of science David C. Lindberg argues that “Alhazen was undoubtedly the most significant figure in the history of optics between antiquity and the seventeenth century.” This is because Ibn al-Haytham successfully integrated not only competing mathematical and physical approaches to light in his new intromission theory of vision, but also harmonized his views on sight with the anatomical work of earlier Muslim physicians. A prolific writer, Ibn al-Haytham is credited with more than 200 treatises on all branches of the sciences, including almost two dozen dealing with light and optics.

Ibn al-Haytham's most important optical work was his *Kitāb-al-manāẓir* (Book of Optics), which was translated into Latin as *De Aspectibus* or *Perspectiva*. This treatise had a profound effect on optics in the Latin West, influencing the work of Witelo (ca. 1230/5–1275), Roger Bacon (ca. 1220–1292), John Pecham (fl. 1250–1292), and many more. Traces of Ibn al-Haytham's theories are even found in the seventeenth century optical writings of Kepler and Newton.

Alongside his intromission theory, Ibn al-Haytham also studied various celestial and atmospheric phenomena such as twilight,

refraction, atmospheric thickness, and optical illusions. He also contributed to the theory of catoptrics and dioptrics and extensively researched the laws of parabolic and spherical mirrors. “Alhazen's problem”, which he solved geometrically, involved taking a spherical mirror and placing an object before it so that its image was reflected in the mirror; to find the point of reflection, one must solve the equivalent of a fourth degree equation. Ibn al-Haytham also demonstrated various reflection laws, including the significant finding that incident, normal and reflected rays all lie in the same plane. In his study of refraction, he discovered the equivalent of Pierre de Fermat's (1601–1665) “principle of least time”: that a ray of light always takes the shortest and easiest path. Much of Ibn al-Haytham's work in this area was based on direct experimentation; glass cylinders immersed in water revealed refraction laws, and homemade lenses helped him determine the laws of magnification. Ibn al-Haytham even did early research into the camera obscura.

Islamic optics declined after Haytham's synthesis, though there was a revival of interest during the rise of the *ishraq* (School of Illumination) in the thirteenth century. ► [Al-Shīrāzī](#) extended Ibn al-Haytham's account of the rainbow, arriving at essentially our modern understanding that its colors are due to a combination of light reflection and refraction through suspended water droplets. Al-Shīrāzī's explanation was confirmed experimentally by his student, al-Farīsī (d. ca. 1320). But by the fifteenth century, leadership in optics had passed to the West, and by the following century, European scientists were making discoveries in physics, astronomy, and mathematics that were to usher in the “Scientific Revolution”.

Physics in China

R. A. Uritam

An account of physics, as well as of any other science, in a prescientific revolution era or civilization does not present a meaningful picture without an understanding of the views of nature that are embedded in various natural philosophies that develop in each civilization and that are the most comprehensive account of natural phenomena before “physics” as a distinct discipline existed. In the West most of these natural philosophies had their origins in Greece, and included Pythagoreanism, Atomism, Platonic idealism and dualism, and Aristotelianism, each of which introduced distinct elements into Western science. However, they largely agreed that the final ground for understanding physical reality was substance, or “stuff.” Additionally, in due course, rational proof, Euclidean geometry, reductionism, mechanistic materialism, and atomism became principal determinants of Western science.

In a similar way at about the middle of the first millennium BCE various schools of natural philosophy arose in China. These included Daoism, Naturalism, Mohism, Legalism, and (much later) Sung Neo-Confucianism. The central concept of Daoism, systematized by Laozi (a contemporary of Aristotle) is the *Dao* (the way), the “way the universe works.” It is the unifying principle of the universe, akin to the “One” of Parmenides. This natural, noncoercive, nonanthropomorphic principle encompasses all phenomena, and invites study of all aspects of nature. Human standards are irrelevant in nature; one is to subject oneself to the harmonies of nature (*wu wei*).

Naturalism, represented by its early proponent, ► [Zou Yan](#) (fl. 300 BCE) introduced the doctrines of Yin and Yang and the *Wuxing* (Five Elements or Phases). Yin and Yang are the two fundamental forces, the expression of

the basic dualistic principle, two forces existing not in conflict, but in a balance or a cooperative tension of opposites. Yang represents light, heat, dryness, hardness, activity, heaven, sun, and south. Yin stands for dark, cold, wetness, softness, quiescence, earth, moon, and north. The Five Elements invite comparison with the four elements of Empedocles. In China the five are water, fire, wood, metal, and earth, representative less of substances than of processes of nature. The elements are further arranged into the Mutual Production Order: wood, fire, earth, metal, water, wood, etc., where each element produces the subsequent one. In the Mutual Conquest Order, each element dominates over the subsequent one.

The less prominent school of Mohism introduced more formal, abstract, and geometrical notions such as a dimensionless geometrical point in space and time. Somewhat in the same vein, the Legalists discussed formal logical propositions, paradoxes, and syllogisms. Curiously, modern Chinese writers during the Cultural Revolution were fond of heaping fulsome praise on the Legalists for their supposed kinship to the scientific materialism of Marxism.

Mohism and Legalism waned in importance, and after centuries of evolution indigenous Chinese natural philosophy reached its most mature form in the twelfth century AD in the Sung neo-Confucian synthesis, best represented by the natural philosopher Zhu Xi (AD 1131–1200). This school combined the attention to nature present in Daoism and Naturalism with the heretofore society-centered official Confucianism that governed human conduct and interaction. In this way the human world and the world of nature were unified and investigation progressed at each “level of integration” from inanimate to human. The synthesis introduced two other fundamental principles of *qi* and *li*, roughly similar to Aristotelean matter and form.

The picture or model of nature that emerges is quite different from the Western one. It is not mechanistic, legalistic, geometrical, linear, or even materialistic. The leading twentieth century student of Chinese science, Joseph Needham, described that picture of nature in China as being one of a harmoniously functioning

organism, an interconnected, interdependent whole. Reductionism and analysis into parts will not yield an understanding of nature because each entity is defined by the role it plays in relation to the pattern it fits into, by the web of relationships it has. The principal element of explanation is not substance but relation and pattern. As in Chinese society, so also in nature there is “order without law”. The legal metaphor is absent in statements about nature (“laws” of nature); the order of nature is not as that of citizens subject to universal law but as that of musicians in an ensemble or dancers in a pattern. For these reasons, traditional Chinese thought found no problem in retroactive causality, since temporal succession is unimportant compared to the interdependence of the system as a whole, as a pattern in space and time.

With a world picture so different from the Western one, it is difficult even to match traditional Chinese activity in some realm with “physics”, itself a term that acquired a recognizable meaning only fairly recently. Nathan Sivin has proposed the following divisions for Chinese science: medicine, alchemy, astrology, geomancy, natural philosophy and physical studies, mathematics, harmonics and acoustics, and mathematical astronomy. Present-day “physics” corresponds to parts of “physical studies” and “harmonics.” Also, the strong and weak branches of physics are reversed in China and in the West. There was no Chinese achievement in mechanics, dynamics, or kinematics, nothing at all to rival Aristotle or the medieval precursors of Galileo. This is consistent with the absence in China of geometrical, corpuscular, and mechanistic ideas. Instead the preference was for continuum theories, pneumatic models, waves, vibrations, and resonances, all consistent with interrelation, pattern, and meaning only for a system as a totality. Thus, the highest achievements in indigenous Chinese physics were in the areas of optics, acoustics, and magnetism. Of the three, optics was the weakest, and ironically, its best practitioners were the Mohists, a school generally atypical of Chinese scientific philosophy. Although, lacking Greek geometry, Chinese optics never attained the level of medieval Islamic optics,

it began at least as early as its Greek counterpart, with an account of light-sources, mirrors, and, later, lenses.

The fourth-century BCE Mohist text *Mo Jing* describes shadow formation, the distinction between umbra and penumbra, and discusses the dependence of the size of the shadow on the position of the object and of the source of light. Properties of light passing through a pinhole are discussed, including the definition of a focal plane and the inversion of the image. Reflection from a plane mirror and from a combination of plane mirrors is treated. Refraction of light at the plane boundary between air and water is described, including the resulting phenomenon of the apparent reduction in depth of an object in water. Also, the formation of images by spherical concave and convex mirrors is discussed in some detail.

Of even greater antiquity in China was the practical use of burning-mirrors for igniting fires from the sun's rays. The earliest such mirrors, made of bronze, date from the Chinese Bronze Age, in the seventh century BCE. A more difficult technological achievement was the production of lenses and burning-lenses. Rock-crystal, i.e., pure transparent quartz (SiO_2) was used; glass was produced as early as the sixth century BCE, and lenses were in use from the time of the Han dynasty of the first century AD. By the tenth century AD the four fundamental types of lenses (plane-concave, biconcave, plano-convex, and biconvex) were produced and their properties analyzed. Eye-glasses and spectacles, as well as magnifying glasses were in use by the fifteenth century AD.

Progress in the fields of sound and acoustics followed naturally from the fundamental orientation of Chinese natural philosophy. The alternation between Yin and Yang implies a cyclic, recurring process between opposites, reminiscent of harmonic oscillation or wave motion. Also, sound was likened to waves in a pool, caused by friction, and to a resonance in the fundamental neo-Confucianist substance, *qi*.

In the description and classification of musical sound and in the construction of instruments, the Chinese displayed their characteristic tendency

to emphasize the whole and the complex, instead of isolating the simple. To Western thought the primary attributes of sound are pitch (frequency) and loudness (amplitude). By contrast, Chinese acoustic theory concentrated from the beginning on timbre (the overtone structure) as the primary attribute or parameter describing sound. Sounds were classified according to timbre according to the "eight sources of sound." metal, stone, earth-clay, skin, silk-thread, wood, gourd, and ► bamboo. As can be expected, these timbres were correlated, like the five elements, with seasons, compass points, and, naturally, musical instruments.

The influence of the concept of pattern and organic unity was at work in the ready acceptance of the spontaneous resonances of two musical instruments, this being merely a corroboration of a resonance in the cosmic organism. In a similar vein, sounds were not classified by pitch; rather, the names of notes in the early five-note scale arose from the mutual arrangement of musical instruments in archaic ceremonies.

A distinctive later achievement of Chinese acoustic theory is less closely related to the organic view of nature. In the sixteenth century AD, Zhu Zaiyou (b. AD 1536) provided the earliest solution to the classic problems of rendering melodies in several keys on one musical instrument, without retuning the pitches. The natural scale is one where the frequencies of the sounds, and the associated lengths of strings in a musical instrument are in "just intonation," following Pythagorean ratios (e.g., 2:1 for octave to tonic, etc.). If the ratios are true for one scale they cannot be so for a scale that begins one note higher. Zhu's solution was to have frequencies of all adjacent notes, differing in pitch by half a tone in a 12-note scale, differ by a ratio $2^{1/2}$ to 1. This system of equal temperament, in use on a modern piano, was introduced considerably later in Europe, becoming popular only in the eighteenth century, and is familiar to music lovers from early examples of its use by composers, such as in Johann Sebastian Bach's *Well-Tempered Klavier*.

The most prominent achievement of traditional Chinese physics, however, was in

magnetism. That phenomenon is totally harmonious with a model of the world as organism, with resonances and intangible influences on the parts from the pattern as a whole. Also, China, not knowing the Aristotelian concepts of natural place, natural and enforced motion, did not have to explain magnetic phenomena, as did the West, as deviations from this scheme. Even more to the point, action at a distance, or the concept of a field, was no problem in China, whereas Cartesian mechanicians saw these as throwbacks to scholasticism when used to account for gravitational, electrical, and magnetic phenomena.

Historically, the discovery of every significant magnetic phenomenon – attraction, directivity, polarity, thermoremanence, declination, as well as application to a working compass – considerably antedates comparable advances in the West. Chinese texts of the third century BCE describe the simplest effect, the attraction of iron by natural magnetite (lodestone). The directional, north-south seeking property of the lodestone was observed about the first century AD and first demonstrated by a lodestone placed on a very smooth bronze surface. (Modern replicas of this arrangement have verified that friction can be made low enough to display the effect.) Subsequently, the lodestone was balanced on a pin, or floated on wood in water. In the early centuries of the first millennium AD the directive property of the lodestone was transferred to iron by rubbing. By the eleventh century AD the more sophisticated method of magnetization, thermoremanence, was in use, consisting of allowing a red-hot piece of iron to cool rapidly through the Curie point while it is oriented along the earth's magnetic field.

By about AD 1100, a useful magnetic compass was in use in navigation, although the traditional inward-looking agrarian economy and dependence on river, rather than ocean, transportation did not thereby lead to extensive global exploration. Beginning in the ninth century AD magnetic declination was observed. Subsequent recordings of declination chronicle a variation of declination over time, for example, the declination being to the east prior to about AD 1050, and to the west after AD 1050.

Philosophers of science differ on whether the fundamental concepts of Chinese natural philosophy, such as relation, pattern, and organism could have furnished an alternative but adequate basis for a model of scientific explanation. On this question, in his extensive writings, Needham has probably overstated the case in favor of the Chinese potential for doing this.

In terms of transmissions from China to the West, the technological contributions are well-known; printing, ► [gunpowder](#), and the magnetic compass are always at the head of the list. Many scholars also attribute to Chinese science a role in promoting the development, after Newton, of nonmechanistic concepts in physics, such as field, wave, fluids such as caloric and ether, to say nothing of the loss of distinction between matter and energy in relativity and between wave and particle in quantum mechanics.

Physics in India

William T. Johnson

Early Indian thinkers developed a number of theoretical systems which centered around two main themes: elements and atoms. Based upon a relatively broad review of the ancient philosophies, we will discover a rich scientific tradition in India.

Ancient India (2000 BCE–AD 800)

Early Indian explanations about the physical makeup of the universe were religious and philosophical in nature. The oldest literary record of this period, the *ṛgveda*, presents several fundamental concepts related to physical science such as *ap* (primeval water), which was considered the basic element of matter. Gradually, the doctrine of five fundamental elements emerged, as seen in the Upaniṣadic literature of around 700 BCE. The five elements were *pṛthvī* (earth), *ap* (water), *tejas* (fire), *vāyu* (air), and *ākāśa* (a nonmaterial substance). The Sanskrit terms have a wider connotation than the English translation, so it is essential to present the original terms.

Much of this early literature was concerned with the attributes associated with each of these elements. They had both common as well as distinctive attributes, many coincident with the five senses, as follows: *pṛthvī* (earth) sound, touch, color, taste, and odor; *ap* (water) sound, touch, color, and taste; *tejas* (fire) sound, touch, and odor; *vāyu* (air) sound and touch; and *ākāśa* (nonmaterial) sound. Different combinations of these five elements yielded certain products. The human body is a good example. The human embryo has energetic principles which are separated into form by *vāyu* (air). *Tejas* (fire) subsequently transforms the embryo. *Ap* (water) maintains moisture while *pṛthvī* (earth) gives it shape and size. Finally *ākāśa* expands the embryo and develops it.

Many of today's scholars question the notion that scientific inquiry only found fertile ground in the minds associated with the Greek tradition. In fact, a number of diverse systems of scientific inquiry were developing in India coincident with the Greek philosophies by 500 BCE. Those which presented five fundamental elements were the *Sāṃkhya*, *Nyāya*, and *Vaiśeṣika*. The *Jaina*, *Bauddha*, and *Cārvāka* schools, like many of the Greek thinkers, presented four fundamental elements. It is difficult to say with certainty which school or culture developed these ideas first, therefore who influenced whom, or if they developed independently.

The *Nyāya-Vaiśeṣika* school, prominent among early Indian systems, was popularized by an individual who came to be known as Kaṇāda. He and his followers extended the concept of five elements and built a comprehensive theory of atoms. The first four elements of this system (*pṛthvī*, *ap*, *tejas*, and *vāyu*) were material and considered either eternal or temporal. The fifth element, *ākāśa*, was considered eternal only. The eternal form consisted of imperceptible atoms, while the temporal form arose when these atoms joined to create perceptible products. This view of five elements was part of a much larger conceptual picture, that of *dravya* (substance). There were nine types of substances. In addition to the five elements or substances already mentioned, there was *dik* (space), *kāla* (time), *ātman* (self), and *manas* (mind). Each of these substances was considered inseparable from its respective set of attributes. In other words, they were one and the same.

The word used for atom was *aṇu* or *pramāṇu*. The *Nyāya-Vaiśeṣika* school held that the atom was indestructible, indivisible, without magnitude, spherical, and in constant motion. Two atoms of the same substance could join to form a dyad. Atoms of different substances could not join together, yet they could play a supportive role in the combination of materially compatible atoms. The dyad was regarded as too small to be perceived. The smallest visible structure was a triad (three dyads). This structure was referred to as *trasareṇu* or *tryaṇuka* which was about the size of a speck floating through a sunbeam.

The principle of causality was crucial to the *Nyāya-Vaiśeṣika* school. Atoms were the material cause for the dyad, the effect. The dyads were the cause for the production of a triad which was another effect. The individual atoms lost their causative property once the triad was formed. The reason for atoms joining in the first place was attributed to *aḍṛṣṭa*, an unseen force.

Jaina philosophers held that atoms were both cause and effect. They theorized that atoms joined to form aggregates in response to attractive and repulsive forces which were inherent characteristics of the atoms themselves. Jaina atoms were all of one class. There was no distinction, qualitatively, or quantitatively, between types of atoms such as earth-atoms, water-atoms, etc. According to the Buddhists, the atom was indivisible, unable to be analyzed, invisible, inaudible, unable to be tested, and intangible. Neither were these atoms eternal. The Buddhists did not speak of atoms in terms of particles. They thought of them as a force of energy.

The *Nyāya-Vaiśeṣika* school was distinct from other Indian schools in that it placed much more emphasis on the attributes of matter. There were five general qualities possessed by all nine substances: number, dimension, distinctness, conjunction, and disjunction. Other qualities, more closely associated with modern physics included, *gurutva* (gravity), *dravatva* (fluidity), *sigdha* (viscosity), and *sthithāpaka* (elasticity). Gravity, or the cause of falling, was not considered a force but a quality which resided in a whole object. No apparent correlation between gravity and the mass of a particular object was presented. Fluidity was a quality of only three substances – earth, water, and fire – and was of two kinds. Natural fluidity was a specific quality of water. Incidental fluidity was associated with fire in the case of some melted substances. Viscosity was specific to water, causing cohesion and smoothness. Elasticity was only a quality of earthy substances as in the branch of a tree which was caused to return to its original condition if displaced. Another fundamental concept considered by ancient Indian thinkers was that of motion.

The *Nyāya-Vaiśeṣika* concept of karma (motion) was represented by three actions: *utkṣepaṇa* (throwing upward), *avakṣepaṇa* (throwing downward), *prasāraṇa* (expansion), *ākuñcana* (contraction), and *gamana* (going). Only one kind of motion was considered possible at a time and a substance experienced motion only for a moment. This motion was subsequently destroyed or rendered ineffective once completed. The motion of free atoms made possible by *aḍṛṣṭa* (unseen force) caused the material world to be formed.

Among Indian physical concepts, that of *ākāśa* should not be overlooked. Its special quality was sound. Though considered a nonmaterial substance, it was believed to play a role in the formation of material objects. A modern physics concept which some have equated with *ākāśa* is that of ether, which is conceived to be a vast expanse or continuum. Sound moved through *ākāśa* like ripples across the surface of a pond. Unlike the ripples, sound moved through *ākāśa* in a succession of points. The first sound caused the second, and once the second sound was created, the first was destroyed.

Heat and light were understood in relation to one of the five basic elements, *tejas* (fire). When an object was heated it went through a series of distinct changes, each one lasting a prescribed number of moments. A clay pot for example, if heated, would in the first moment experience the production of atomic motion. The second moment would be characterized by the destruction of the clay's original color. In the third and fourth moments one would find that the color red would be produced followed by the destruction of the atomic motion created earlier. A new type of atomic motion, creative in nature, occurred in the fifth moment. A series of two disjunctions between the atoms and *ākāśa* was followed by a conjunction in the sixth through eighth moments. The final two moments consisted of the formation of a red colored dyad followed by a triad. The ultimate source of all heat was thought to be the sun. Light, though often associated with heat in many modern physical systems, possessed many qualities, distinctive from heat, in the early Indian systems.

Light was thought to consist of rays which emanated from the eyes just as a candle casts its light throughout a room. If an obstruction prevented the rays from touching an object, then that object simply could not be perceived. Mirrors were thought to possess particular attributes of color which caused the light rays from one's eyes to return to one's face upon striking the surface.

Medieval India (AD 800–1800)

It is a common misconception that there was a lack of scientific inquiry during the Middle Ages. While India experienced great change during this time, such as the introduction of Islam, there was a continued advance and assimilation of scientific information with an ever increasing number of collaborators. New cultural influences, changing technologies, and language barriers challenged as well as fostered scientific advances.

Physics was viewed as a distinct branch of study during the early part of the Middle Ages. Though experiments were still quite rare, use of this scientific technique began. A large number of texts were translated into different languages. A scholar named ► [Ḥunayn ibn Ishāq](#) translated Aristotle's works into Syriac and his son Ishāq ibn Ḥunayn followed suit, translating Euclid's *Elements*. Ideas were shared, expanded upon, and refined. A number of original inquiries were also initiated.

Among the more notable individuals describing physics research in India as well as Middle Asia at this time was Abū Rayḥān ► [al-Bīrūnī](#). He authored many books devoted to the scientific achievements of the Indian people.

The latter part of this period experienced an influx of European influences. Educational institutions, scientific journals, and professional societies each played a role in the development of what was to become modern India. New political and economic structures, in the face of new language barriers between the educated few and the illiterate masses, threatened to disassemble the rich scientific heritage of the Indian people. Yet India assimilated the old and the new to

emerge strong with an outstanding future of scientific inquiry before it. Much of that future rested in the hands of a few visionaries who understood the significance of science in India's future.

Modern India (AD 1800–Present)

The outstanding efforts of many have contributed to India's rich past and promising future. The following few individuals are some of the physicists who have exemplified the level of achievement found throughout modern India.

Jagdish Chandra Bose (1858–1937) was a biophysicist who explored the response of plants and animals to electrical stimulation. Like many pioneering physicists active at the turn of the century, Bose used instruments of his own design in his work. He was elected a Fellow of the Royal Society of London in 1920. C. V. Raman (1888–1970) investigated optics, including diffraction, molecular scattering of light, and magneto-optics. He was awarded the Nobel Prize in 1930 for the discovery which bears his name, the Raman Effect. This pioneering work described the molecular scattering of light and explained, among other things, why the ocean appears blue. Finally, Jawaharlal Nehru, the first Prime Minister of India, worked hard to foster what he described as a “scientific temper.” He believed that for science to succeed in modern India, as it had in its past, there had to be strong support for the scientific enterprise from all segments of society.

The history of physics in India is a vast subject, offering extensive opportunities for further study. It is hoped that this brief presentation has encouraged some to explore the ancient philosophies, medieval refinements, and modern achievements.

Physics in the Islamic World

Timothy J. McGrew

With the rapid expansion of the Arabian tribes into western Asia and northern Africa in the early seventh century, the Islamic world fell heir to the documentary remains of Greek science and mathematics. Scientific research had grounded to a halt in the Byzantine Empire, and in a very real sense the intellectual center of gravity was transferred to the East, where, despite occasional upheavals, learning flourished

under a series of enlightened patrons for over 500 years.

In contemporary usage, the word “physics” denotes an autonomous and highly specialized branch of science which deals with the behavior of non-living systems, bringing them under the scope of the most general natural laws. There was no parallel to this discipline in medieval Islam, yet from the eighth century onwards there was a profusion of translations, commentaries, and learned writings on topics which would today fall under the broad heading of physics.

The contributions of Islamic thinkers to astronomy and mathematics were of the first importance. Optics, which would today be considered a branch of physics, was studied in close conjunction with both geometry and medicine, since various problems regarding vision remained unresolved in the Greek scientific literature. The contributions of Ibn al-Haytham to the problem of refraction are particularly noteworthy.

Astronomy and optics aside, Islamic scholars wrote profusely on the nature of matter, causality, the theory, and practice of mechanics, and dynamics.

The Nature of Matter and Causal Laws

The dominant philosophical school in Islamic physics was the Aristotelians or *Falāsifa*. Prominent members of this school included al-Kindī (d. 873), al-Fārābī (d. ca. 950), Ibn Sīnā (Avicenna, d. 1037), and Ibn Bājjā (d. 1138). While the *Falāsifa* held Aristotle in the highest respect, their work was somewhat syncretistic. The Greek philosophical corpus was often taken to be an integrated whole, and diverse elements of Plato and the Neoplatonists found their way into the synthesis of the Arabic Aristotelians. Al-Fārābī went so far as to write a book entitled *Jamʿ bayna raʾyay al-ḥakīmayn Aflātūn al-ilāhī wa-Aristūṭālīs* (The Harmony between Plato and Aristotle). Most Arabic scholars who sought to reconcile these strands of thought relied heavily on a work known as the *Theology of Aristotle*, in which Aristotle

himself seemed to provide a bridge between his technical and logically rigorous work and the more literary and imaginative work of Plato. But modern scholarship has established that the *Theology* was wrongly attributed to Aristotle and is actually a compendium of the writings of the Neoplatonist Plotinus.

In physics, the doctrine held that every object could be analyzed as a composite of matter, which is the locus of its potency or possibilities, and form, which is the actualization of some of those potencies. Matter, like space itself, was believed to be infinitely divisible. Physical bodies behaved in qualitatively predictable ways because of their innate tendencies. Hence, a stone falls because it seeks its natural place at the center of the earth, and water seeks its lowest level in lakes and oceans because its attraction to the center of the earth is slightly less strong than that of the stone.

The infinite divisibility of space led to some perplexing dynamical difficulties, first noted by the Greek philosopher Zeno of Elea, which induced some Islamic physicists to question the coherence of the Aristotelian concept of space.

► **Al-Bīrūnī** (d. after 1050), a prominent critic of Aristotelian physics, posed this dilemma in a letter to Ibn Sīnā: If the sun is west of the moon in the sky, with a definite space between them, then even though the moon moves much faster than the sun, it should never be able to catch it. For the space between them can be conceived as divisible into an infinite number of parts; but how can a body moving with a finite speed cross an infinite number of spaces? In al-Bīrūnī's view, this paradoxical consequence reflected poorly on the Aristotelian concept of the infinite divisibility of space. After all, anyone can see that the moon does in fact overtake the sun.

A competing school of thought was inspired by Sunni theology, with its strict insistence on divine omnipotence. In this view, all bodies consist of a finite number of indivisible atoms, and the behavior of these atoms is not the consequence of any causal relations between them but is governed directly by the divine will. What appear to be causal connections are only regularities which we are in the habit of calling laws;

there is no connection discoverable by reason between separate events, and Aristotelian explanations for the behavior of bodies in terms of natural tendencies are therefore hopelessly misguided.

The controversy between the theologians and the Aristotelians came to its climax in the *Tahāfut al-Falāsifa* (Self-Destruction of the Aristotelians) of al-Ghazālī (ca. 1058–1111), in which he maintained that philosophers could not know, for example, that fire causes cloth to burst into flame but only that the combustion of the cloth occurs at the moment that it makes contact with the flame. Ibn Rushd (ca. 1126–1198) responded with a *Tahāfut al-Tahāfut* (Self-destruction of the Self-destruction) in which he claimed that such skepticism regarding the efficacy of reason would undermine itself. In contemporary philosophy of science, a similar controversy is still raging over the nature of causality and our knowledge of causal connections, though the arguments arise not out of theological considerations but rather from Hume's skeptical doubts about induction and the verificationism of the logical positivists.

Mechanics

One of the simplest of mechanical devices, the lever, had been investigated mathematically by the Greek polymath Archimedes, who gave an elegant proof that the forces required to keep the unequal arms of a lever in balance were inversely proportionate to the length of the arms. In the course of his proof, Archimedes assumed that two equal weights located at different points on one arm of the lever produced the same effect as if they were both located at the midpoint between them – an assumption which is intuitively plausible but for which he gave no rigorous justification. ► **Thābit ibn Qurra** (d. 901) provided an intriguing argument for this assumption in his *Kitāb al-qarastūn* (Book of the Balance).

The balance was investigated very thoroughly in Islam. Al-Bīrūnī worked out a general method for determining the specific gravity of an irregular solid which he published in his *Maqala fi'l-ḥisab allatī bayn al-filizzāt*

wa'l-jawāhir fi'l-hajm (Treatise on the Ratios Between the Volumes of Metals and Jewels). In later years, the best-known work on the subject was the *Kitāb mīzān al-ḥikma* (Book of the Balance of Wisdom) of ► [al-Khāzinī](#) (fl. ca. 1115–1130), a careful though not very original treatise which covers the theory of balances (relying heavily on the work of al-Bīrūnī), the practical details of their construction, and their use for determining proportions of metals in alloys. In the course of his discussion, al-Khāzinī notes that heat decreases the density of metal objects. The *Kitāb* of al-Khāzinī is among other things a source of alchemical lore, and it is no accident that it became a standard text on the construction of equipment among alchemists in succeeding generations.

Islamic scientists were aware of more complex mechanical contraptions, and a few works described windmills, clocks, and other marvelous devices. The most lavishly illustrated volume on this subject, the *Kitāb fī ma'rifat al-ḥiyal al-handasiyya* (Book of Knowledge of Ingenious Mechanical Devices) of ► [al-Jazarī](#), describes some 50 mechanical devices including several different types of fountains. But they made no systematic effort to apply the principles utilized in these devices on a broad scale. The knowledge of the principles of mechanics did not generate a technological revolution.

Dynamics

The Aristotelian theory of motion was a source of considerable difficulty for Islamic thinkers. Apart from the “natural motion” by which objects seek their natural place, the Aristotelians viewed motion as the result of the application of a force. In the absence of the force, motion ceases, as a cart grinds to a halt when the rope connecting it to the horse is broken. But this commonsense theory generates serious problems when applied to projectile motion. Why should a flung stone hurtle through the air when it leaves the hand? Why should an arrow continue to fly when it has left the bowstring? Aristotle’s own suggestion was that somehow the air rushes around to the

rear of the object in a way which prolongs its flight. But this was both vague and apparently irreconcilable with the facts; the flight of a javelin is not appreciably improved by design changes at its back end which would help it to “catch” the air.

In place of this unsatisfactory explanation, Ibn Sīnā and Abū'l-Barakāt al-Baghdādī (ca. 1080–ca. 1165) developed a theory of “violent inclination” which matches very closely the impetus theory first suggested by the Alexandrian Neoplatonist John Philoponus (d. ca. 570) and which was widely held until the seventeenth century. According to this theory, the agent of motion (the hand which flings a stone, for instance) imparts to the object a temporary inclination to continue moving, an inclination which partly counteracts the tendency of the object to seek its natural place and which is gradually dissipated through its flight.

Aristotle’s notions regarding free fall also came under critical scrutiny by Islamic thinkers. According to Aristotle (*Physics*, Book 4, chapter 8), the motion of a falling object is directly proportional to its natural inclination (the tendency it has to seek its natural place) and inversely proportional to the resistance offered by the medium through which it moves, an account which strongly suggests the mathematical formulation

$$M \propto \frac{F}{R},$$

where M is motion, F is force and R is the resistance. Ibn Bājja (better known in the West as Avempace), though working within the broadly Aristotelian framework, criticized this view on the grounds that, if Aristotle’s account were correct, unresisted motion (such as that of the heavenly bodies) would be instantaneous – which it clearly is not. In place of the Aristotelian law of motion, he suggests the formula

$$M \propto F - R,$$

which has the advantages that motion in the absence of resistance need not be instantaneous

but rather proportional to the impressed force, and that when force and resistance are balanced, the result is not motion at all but cancellation of motion. Ibn Bājja's views here closely resemble some arguments advanced earlier by John Philoponus, but it was through Ibn Bājja's writings, preserved in a commentary on Aristotle's *Physics* by Ibn Rushd, that these views were transferred to the west and influenced the early work of Galileo.

Abū'l-Barakāt's reflections on motion in his *Kitāb al-Mu'tabar* (Book of What has been Established by Personal Reflection) are also remarkable as precursors of a radical departure from the Aristotelian view. In explaining the motion of a flung stone, he appeals not only to the dissipation of the violent inclination but also to a compounding of successive natural inclinations which increases the overall strength of the natural inclination during the fall. This idea of the compounding of the force through small intervals represents a serious advance over Aristotle's view that the distance travelled by an object in free fall per unit time is directly proportional to the weight of the object. It appears not to have occurred to Aristotle to consider the question of instantaneous velocity. Abū'l-Barakāt's explanation for free fall is thus one of the first hints that the constant action of a force might produce not merely motion but an acceleration.

Pi in Chinese Mathematics

Lam Lay Yong

In the earliest existing mathematical texts, ► [Zhoubi suanjing](#) (The Mathematical Classic of the Zhou Gnomon) and ► [Jiuzhang suanshu](#) (Nine Chapters on the Mathematical Art), the ratio of the circumference of the circle to its diameter, or π , was taken to be three. Liu Xin, who lived in the first century BCE and was an astronomer and an expert on calendrical calculations, was mentioned in *Suishu* (Standard History of the Sui Dynasty) as being among the earliest to improve on this value. This arose from the construction of a standard measure called *jia lianghu* which he prepared for Emperor Wang Mang.

In his commentary on a problem concerning a sphere in *Jiuzhang suanshu*, Liu Hui of the third century referred to Zhang Heng's (AD 78–139) empirical deduction which implied a value of $\sqrt{10}$ for pi. The eighth century book, *Kaiyuan*

zhanjing (Kai Yuan Treatise on Astrology), expressed Zhang Heng's estimation in the ratio of 736–232. A century later, Wang Fan improved this to the ratio of 142–45.

However, it was Wang Fan's contemporary, Liu Hui, who succeeded not only in attaining a better estimate for pi, but also in writing down the detailed method of how he arrived at the result.

His method commenced with a regular hexagon inscribed in a circle. This was extended to a 12-sided polygon where the length of one side and its area were calculated from the hexagon based on the properties of the right-angled triangle. Next, a polygon of 24 sides was constructed and the length of its side and its area were calculated from the data of the dodecagon. Regular polygons inscribed in the circle were in this manner continuously constructed; the number of sides of one polygon was always double that of the previous polygon and the area of a polygon was formulated as one half the perimeter of the previous polygon multiplied by the radius of the circle. Liu Hui pointed out that if this process was repeated long enough, eventually there would be a polygon whose sides were so short that they would coincide with the circle. He concluded that this explained why the area of a circle was one half the circumference multiplied by the radius. He further pointed out that when the ratio of the circumference to the diameter was taken as 3–1, this value was in fact the ratio of the perimeter of the hexagon to the diameter.

Liu Hui reached a polygon of 192 sides when he calculated pi to lie between 3.14 64/625 and 3.14 169/625. From these figures he deduced an approximate value for pi of 157/50 or 3.14. He gave another value of 3927/1250 or 3.1416 which he said could be verified when calculations reached the polygon of 3,072 sides.

Computations were performed through the rod numeral system which was not only a medium for whole numbers but also one for common fractions and decimal fractions. The knowledge of Liu Hui's method and the rod numeral system would enable the value of pi to be calculated to

any desired degree of accuracy. It was therefore not surprising that ► [Zu Chongzhi](#) (AD 430–501), the most distinguished mathematician, astronomer and engineer of his time, found π to lie between 3.1415926 and 3.1415927 and also gave it a value of 355/113. These values were not surpassed until a thousand years later when al-Kāshī evaluated pi correctly to sixteen decimal places. Zu's values were recorded in *Suishu* but no method was given, and Zu's own work had long been lost.

PI in Indian Mathematics

R. C. Gupta

Undoubtedly π or π is the most interesting number in mathematics, and its history will remain a never-ending story. It occurs in several formulas of mensuration and is variously involved in many branches of mathematics, including geometry, trigonometry, and analysis.

The earliest association of π is found in connection with the mensuration of a circle. The fact that the perimeter or circumference of any circle increases in proportion to its diameter was noted quite early. In other words, in every circle, perimeter/diameter = constant, or $p/d = \pi_1$, where π_1 is the same for all circles.

After knowing the perimeter, the area of the circle was often found by using the sophisticated relation

$$\text{area} = \left(\frac{p}{2}\right) \left(\frac{d}{2}\right) = \frac{pd}{4}.$$

But the earliest rules for determining area were of the form $\text{area} = (kd)^2$, where k is a constant prescribed variously. Both these methods imply that the area of a circle is proportional to the square of its diameter (or radius r), or $\text{area} = \pi_2 r^2$.

We know that π_2 is the same as π_1 , but this was not always known. Similarly, π_3 may be defined from the volume of a sphere. In this article, the symbol π is used to denote all the above three values, as well as for their common value, which is now known to be not only an irrational, but also a transcendental number.

Since the Indus Valley script has not been deciphered successfully, we cannot say any final thing about the scientific knowledge of India of that time (about the third millennium BCE). Some conjectures about the value of π used in the *R̥gveda* (about the second millennium BCE)

have been made. Definite literary evidence is available from texts related to *Vedāṅgas*, especially the *Śulbasūtras* which contain much older traditional material. In the ► *Baudhāyana Śulbasūtra*, the oldest of them, the perimeter of a pit is mentioned to be three times its diameter, thereby implying $\pi_1 = 3$. This simplest approximation is found in almost all ancient cultures of the world. In India, it is found also in classical religious works such as *Mahābhārata* (Bhīṣmaparva, XII: 44), and certain *Purāṇas*, as well as in some Buddhist and Jain canonical works.

Different approximations to π_2 are implied in the various Vedic rules for converting a square into a circle of equal area and vice versa. If r is the radius of the circle equivalent to a square of side s , the usual *Śulba* rule is to take $r = s(2 + \sqrt{2})/6$, which implies the approximation $\pi_2 = 18(3 - 2\sqrt{2}) = 3.088$. Recently, a new interpretation of the *Mānava Śulba Sūtra* has yielded the relation $r = 4s/5\sqrt{2}$, thereby implying $\pi_2 = 25/8 = 3.152$, which is the best *Śulba* approximation found so far.

The ancient Jain School preferred the approximation $\pi = \sqrt{10}$, which they considered accurate and from which they derived the value $\pi = \sqrt{3^2 + 1} \approx 3 + 1/6 = 19/6$. This value ($\sqrt{10}$) continued to be used in India not only by the Jains but also by others, such as ► *Varāhamihira*, ► *Brahmagupta*, and ► *Śrīdhara*, even when better values were known.

With Āryabhaṭa I (born AD 476), a new era of science began in India. In the *Āryabhaṭīya*, he gave a fine approximation of π_1 , surpassing all older values. It contains the rule that the perimeter of a circle of diameter 20,000 is close to 62,832, so that $\pi_1 = 62,832/20,000 = 3.1416$ nearly, which is correct to four decimal places, and he still calls it close and not exact.

This value had a respectful place in Indian mathematics and exerted greater influence. How ► *Āryabhaṭa* obtained it is not known. It was known in China, but evidence of borrowing lacks documentary support. On the other hand, the two typically Indian values $\sqrt{10}$ and

62,832/20,000 appear in many subsequent Arabic works.

In India, the Archimedean value $22/7$ for π first appeared in the lost part of Śrīdhara's *Pāṭī* (ca. AD 750). A Jain writer, Vīrasena, quotes a peculiar rule in his commentary *Dhavalā* (AD 816). It is equivalent to $\rho = 3d + (16d + 16)/113$. If we leave out the redundant dimensionless number +16 in the brackets, this rule will imply a knowledge of the value $\pi_1 = 355/113$ which was known in China to ► [Zu Chongzhi](#) (AD 429–500). In explicit form, this value is found in India much later, e.g., in the works of Narāyaṇa II, Nīlakaṇṭha, and others. The simplified or reduced form 3,927/1,250 of Āryabhaṭa's value of π occurs in the works of Pauliśa, ► [Lalla](#), Bhaṭṭotpala, and the great ► [Bhāskara II](#).

Most significant contributions on the computations of π were made by the mathematicians of the late Āryabhaṭa School of South India. Mādhava of Saṅgamagrāma (ca. AD 1340–1425), the first great scholar and founder of the School, gave the value $\pi_1 = (2, 827, 4, 333, 8, 823, 3)/(9 \times 10^1)$ as known to the “learned men”. This value yields an approximation correct to 11 decimals. Mādhava also knew the series $\pi/4 = 1 - 1/3 + 1/5 - 1/7 + \dots$ which was rediscovered in Europe in 1673 by Leibniz.

In discovering various series for π and in evolving techniques for improving their convergence, a great theoretical breakthrough was attained in sixteenth-century India.

Pirī Reis

Sevim Tekeli

Pirī Reis, Muhyī al-Dīn Pirī (1465–1554), was born in Gallipoli, a naval base along the Marmara coast. He was an important admiral, cartographer, and geographer of his time. His fame depends on two world maps and a book named *Kitāb-i Bahriye*.

The First World Map (1513)

In 1929 a map was found in Topkapi Palace, on a piece of parchment 90 × 60 cm in size. It had

been drawn in 1513, and later presented to Sultan Selim in 1517 in Egypt. This portion shows only the coast of South Western Europe, West Africa, the Middle East, and Central America. On the map, mountains were drawn in outlines, and the rivers marked with thick lines. Shallow places were indicated by red dots, and rocky places in the sea with crosses. Notes were added concerning different regions, and they were decorated with illustrations of special plants, and animals.

This map is a *portolano*, a navigation manual illustrated with charts, with no lines of longitude and latitude. Instead there are two wind roses, one in the North and the other in the South. Each of these roses is divided into 32 parts, and lines are extended beyond these roses; there are two scales indicating mileage. The lines that are extended from the wind roses and the scales are used in measuring the distances between the ports.

Pirî Reis made use of 34 maps in drawing his own. Of these, 20 had no dates. Eight of them were maps that were called *Jaferiyye* by Muslim geographers. Four were new maps drawn by the Portuguese, and one was the map of Christopher Columbus. Since this last is now lost, the only original document we have today is the map of Pirî Reis. When he was drawing the coasts of America, he remained faithful to Columbus' map, and copied it from several points. The Antilles and Cuba are shown as continents on his map, which was what Columbus believed. When Columbus was near the coast of Cuba in 1494, he had the firm belief that Cuba was a continent. As a result, he had his conviction recorded by the notary public on board, Ferdinand Perez de Luna, and asked all the crew to sign it. Columbus had shown South America as a group of islands. Inspired by this, Pirî too drew lot of imaginary islands opposite Trinidad. This map is a very valuable historical map for two reasons. First of all, it was the most correct and scientific map of the time, and secondly it was the only map which was drawn using Columbus' map, of which neither the original nor the copy exists today.

The Second World Map (1528)

Fifteen years after his first map, Pirî Reis drew a second world map. Today we have only a small portion of it, 68 × 69 cm in size. On this portion, there are the northern parts of the Atlantic Ocean and the newly discovered regions of North and Central America.

The map starts with Greenland, in the north. Toward the south there are two pieces of land. The first is called Baccalo; the second one, further down, is called Terra Nova, and it is mentioned that these were discovered by the Portuguese. Further south there is the peninsula of Florida drawn quite correctly. The pieces of land at the side are the peninsulas of Honduras and Yucatan, discovered in 1517 and 1519, respectively.

Cuba and Haiti are drawn quite accurately. The errors on the previous map were corrected on this one.

There is a slight distortion on the map from the true positions as we know them today. This error was committed because of neglect in not taking into consideration the 10–13° of difference in angle on contemporary compasses. This error is true for all Western-originated maps.

In this second map, the drawing of the coastlines shows greater improvement when compared with the inaccuracies of the first one. Only the parts of the world that were discovered were shown; the unexplored areas were left blank.

Kitâb-i Bahriye

Pirî made a book of all his notes, revised and expanded it, and in 1525 presented it to Süleyman the Magnificent. He analyzed the geographic works of his time and, with his sharp faculties of observation, he set down everything he came across in his travels. In the preface of his book, he said that his purpose in writing such a book was to give information about ports, coasts, and islands by drawing them on maps known as *portolanos* in the west. However, he added that no matter how big the scales of maps were, it was impossible to show enough of the vital details on them. This lack of important information made him see the

necessity of writing a book to compensate for this insufficiency. This, then, is the novelty *Bahriye* brought to the science of navigation.

bodies share the property that they move through the background of fixed stars in a west to east direction, although at vastly different speeds. In addition, all of the planets move through a fairly narrow band of stars, the zodiacal constellations, which lie in a plane tilted about 24° from the celestial equator. Both of these properties, and in addition the fact that the fixed stars and all the planets also share a daily rotation of the celestial sphere in the east to west direction, are plainly visible to the unaided eye and certainly were a significant factor in the interactions of people with their natural surroundings for thousands of years.

Eventually written records of the movements of the planets through the fixed stars began to be kept. For example, we have astronomical diaries from Babylon for much of the first millennium BCE that note the days when some planet is near some bright zodiacal fixed star and the days when some planet became first visible at sunrise and last visible at sunset. Eventually, mathematical models of these occurrences were developed which enabled the prediction of the same events in the future, and astronomy of the planets as we understand it today began to develop. Along with the models of the risings and settings of the star-planets, even more detailed models of the movements of the Sun and Moon were developed that enabled the prediction of events important to establishing the calendar of civil life, namely, the days that mark the first and last appearances of the Moon around the times of new moon and full moon.

The key mathematical ingredients to these early models are the period relations. These are numerical statements that tell the number of years required for the completion of some integral number of some celestial event. An example is the empirical fact that in 83 years Jupiter will pass by some bright reference star, perhaps Regulus, seven times.

Beyond these period relations, which define only average speeds for the planets, is the important realization that the speed of each planet is not, in fact, constant, but rather variable. These variations in speed come in two varieties. First, the speed of a planet as it traverses its path

Planetary Models in India

Dennis Duke

Florida State University, Tallahassee, FL, USA

For ancient astronomers, the planets were the two luminaries, the Sun and the Moon, plus the five visible wandering stars, Mercury, Venus, Mars, Jupiter, and Saturn. All seven of these celestial

through the zodiac is sometimes faster and sometimes slower. Such a speed variation on the part of the Sun is the cause behind the empirical observation that the length of our four seasons is unequal, and similarly, variations in the speed of the Moon cause some months to be shorter than average while some months are longer. Second, in the case of the five star-planets, the planet from time to time appears literally to stop its forward west-to-east motion, then to reverse and go east to west for some time, and then to stop and resume its normal west-to-east progress through the zodiac. This retrograde motion is also coincident with the time that the planet and the Sun are on opposite sides of the Earth.

Thus, the final stage of planetary model development was to address the two major problems, the variation of speed through the zodiac and, in the case of the star-planets, the correlation of the retrograde motion with oppositions to the Sun. As it happens, this development was not only arithmetical but geometrical, thus enabling the ancient astronomers to predict the future position on the celestial sphere of all planets at any moment in time.

As far as we can tell from the surviving historical record, this final development was begun in the second half of the first millennium BCE and completed early in the first half of the first millennium CE. The surviving records show similar models for planetary motion in Greek (and later Greco-Roman) cultures and later also in the Hindu culture of India.

The Greek planetary models are thoroughly documented in Ptolemy's *Almagest*, written probably around 150 CE, although it is likely that much of the development of these models preceded Ptolemy. The corresponding Hindu models first appear in the *Paitāmahasiddhānta*, probably written in the mid-fifth century CE, and in Āryabhaṭa's *Āryabhaṭīya*, probably written around 500 CE. In the case of these Hindu models, the texts are very terse and contain little or no explanation of the development of the models.

The first step in the determination of the position of a planet is to compute the mean longitude. This is the longitude that the planet would have if

its speed was not varying, either zodiacally or in retrograde. To compute the mean longitude for any moment in time requires knowledge of the mean longitude at some fixed reference (or epoch) time, to which is added the progress from that reference longitude during the time interval. The progress is, of course, just the product of the average speed and the time interval. The average speeds, also known as mean motions, of the planets are generally expressed as ratios of relatively small integers by the Babylonians and Greeks, but the early Hindu texts instead given ratios of very large integers. For example, for Saturn, while the Greeks would give 2 revolutions in 59 years, the *Āryabhaṭīya* gives 146,564 revolutions in 4,320,000 years, and the *Paitāmahasiddhānta* gives the larger pair 146,567,298 revolutions in 4,320,000,000 years.

These huge time periods are known as *yugas*, or Great Year intervals, and are used in a broader sense as the basis for cosmic time that says the universe goes through endless cycles of creation, destruction, and rebirth. At the beginning and end of the cycle and, depending on the details, at various subperiods in between, all of the planets are perfectly aligned.

While either set of larger numbers might suggest a more accurate mean motion than the Greek pair, they are in fact less accurate. The Hindu ratios in fact are based on just two pieces of information: first, an approximation to the Greek ratio and, second, a value of the mean longitude at epoch that is known only to fall within an interval of just over 1° in width for the *Āryabhaṭīya* and $\frac{1}{4}^\circ$ in width for the *Paitāmahasiddhānta*. The result of these approximations is that the mean longitudes can be moderately accurate for a few decades around the epoch time, but their accuracy degenerates quickly with time. Hindu astronomers of the late first and early second millennium CE were aware of these problems, and every few centuries would suggest correction terms to the mean motions to keep the models coordinated with reality.

Having determined mean longitudes, the next step is to determine the correction terms due to nonuniform motion. These terms are added to the mean longitudes to determine the true

(observable) longitudes. In the *Almagest*, the mechanism for achieving the nonuniform motion around the zodiac is an eccentric circular orbit (or the equivalent epicycle model). In such an orbit, although the planet is moving around the circle at a uniform speed as seen from the center of the circle, the Earth is not at the center but at some nearby eccentric position. From this off-center position, the speed of the planet appears to be slower when the planet is farthest from the Earth (at apogee) and fastest when the planet is closest (at perigee). By adjusting the amount of eccentricity, the ratio of minimum to maximum speed can be adjusted to match the observed variation of the planet's speed around the zodiac. The solar model used by the Hindu astronomers was the concentric equant, in which the Earth is at the center of the Sun's orbit and the motion of the Sun is uniform as seen from an eccentric point.

The situation for the Moon is somewhat more involved. When the Moon is near syzygy (new moon or full moon), the Greek model is the eccentric used for the Sun, but with a larger eccentricity, and similarly, the Hindu model uses the concentric equant. But when the Moon is not near syzygy, the effective eccentricity is even larger. This second anomaly due to the varying eccentricity was included by Ptolemy but is missing in the early Hindu texts. However, it does appear in a Hindu text attributed to Muñjāla, probably written around 930 CE, and his version is, in fact, a significant improvement over Ptolemy's treatment.

For Venus, Mars, Jupiter, and Saturn, the *Almagest* model is the equant plus an epicycle. The equant accounts for the zodiacal anomaly. The epicycle center moves around a circle and the Earth is offset from the center. However, the motion of the epicycle center appears uniform not from the center but from an equant point offset from the center. This offset is equal to the offset of the Earth, but in the opposite direction. Then, the planet itself moves counterclockwise around the epicycle so that the radius of the epicycle is always parallel to the direction from the earth to the Sun, thus providing the required retrograde motion and the coordination with the Sun's position.

The Hindu model for the star-planets involves a four-step process. First, a concentric equant is used to compute a zodiacal anomaly for the planet. Second, half of this anomaly is used to compute a solar anomaly for the planet using a simple eccentric model, which is itself subsequently halved. Third and fourth, these two steps are repeated without the halving, giving the final answer. Although it is hardly obvious, detailed numerical and analytic calculations show that for small to moderate sizes of the eccentricity and the epicycle radius, the Hindu four-step model is an excellent approximation to the *Almagest* equant plus epicycle model, but it is definitely not a good approximation to the eccentric plus epicycle model.

There is no evidence that the Hindu astronomers were aware that the four-step method approximates the equant, and the Hindu texts are, as they are on every other subject, completely silent regarding the motivation to use the four-step approximation. One plausible motivation regards the practical computation, which is usually done with tables. For the *Almagest* equant, the anomaly associated with retrograde motion is a function of two variables, and to compute this in the *Almagest* a rather sophisticated interpolation scheme is introduced, and no such scheme is ever mentioned in any Hindu text. However, in the four-step method, both the zodiacal anomaly and the retrograde anomaly are simple functions of one variable, and so practical computation with tables is much simpler. Thus, it is not unreasonable to entertain the idea that not only the equant but also the four-step method is of Greco-Roman origin.

The Greek and Hindu models for the latitude of the Moon simply tilt the orbit a few degrees from the ecliptic. However, the latitude models of the star-planets in the *Almagest* are much more complicated. The planet orbits and epicycles execute various periodic tilting motions that result in changes in latitude so small that they were probably difficult if not impossible to even observe with naked-eye observations. However, Ptolemy also wrote a much shorter exposition of the planetary models called the *Planetary Hypotheses* in which the planetary latitudes are like the Moon's,

a fixed tilt of the orbit from the ecliptic. These are exactly the models found in the Hindu texts. The *Planetary Hypotheses* also gives mean motions in terms of large integers, but those have none of the underlying simple structure of the large number ratios found in the Hindu texts.

An important application of the planetary models was the computation of the time of conjunction or opposition of a pair of planets, for example, the Sun and the Moon for eclipses or Jupiter and the Sun for retrograde motion. To compute the time, the standard method was to begin with the (easily computed) time of conjunction of the mean longitudes and then to determine at that moment the difference of the true longitudes. Then, if you know the true speeds of each planet, as opposed to the mean speeds, it is easy to estimate when they will be in true conjunction. To do this, you need what we call the time derivative of the two anomaly terms, and it is remarkable that we find in the *Almagest* explicit estimation of these derivatives using finite difference approximations. Even more remarkable is the fact that the anomaly terms are functions of a second function, and so the computation of the derivative requires the chain rule of differential calculus, and this is also estimated correctly by finite differences in the *Almagest*. Finally, these same finite difference approximations are found in many later Hindu texts such as the *Sūryasiddhānta* (ca. 1250 CE), but not in the earlier *Paitāmahasiddhānta* or *Āryabhaṭīya*. A badly garbled version might be present in the *Brāhmasphuṭasiddhānta* (ca. 650 CE), but this is uncertain.

Regarding the mathematical astronomy of the planets, it has been widely thought that the sophisticated astronomy of the *Almagest* was not reflected in any Hindu text. Nevertheless, there are a large number of similarities between Greek and Hindu astronomy, many of them technical or linguistic, and so unlikely to be coincidences. Thus, most Western scholars who have looked at the Hindu texts have not hesitated to conclude that Hindu astronomy was influenced by the transmission of Greek astronomy in the centuries following the invasion by Alexander the Great and that Greek astronomy must have

come from pre-Ptolemaic sources that have not come down to us in modern times.

On the other hand, many modern Hindu scholars have argued that since early Hindu astronomy is not influenced by the *Almagest* and that there are many things that are not (they thought) similar to Greek astronomy, there is no good reason to doubt that it was developed in India, and in fact Hindu astronomy might have to some degree influenced both Greek and Babylonian astronomy, thus accounting for the many observed similarities.

It is now clear, however, that both views require some reconsideration. The principal examples of astronomical differences have always been the planetary models discussed above. All of the major elements of the Hindu models were considered by both Western and Hindu scholars to be pre-*Almagest* and not present in Greek astronomy. These include the expression of the mean motions with large integers related to a yuga or Great Year time interval, the treatment of the zodiacal and solar anomalies with the four-step method instead of the equant, the second lunar anomaly, the planetary latitudes, and the true speeds of the planets.

Regarding the Hindu mean motions using the Great Year concept, recent studies have revealed similar schemes in Greek astronomy in the late first millennium BCE, long before the detailed scheme of the *Paitāmahasiddhānta* first appeared in the fifth century CE. Also, regardless of the appearance suggested by the large numbers in Hindu astronomy, they are all constructed from fairly rough approximations that were certainly known in Greek astronomy in the late first millennium BC.

Similarly, the fact that the Hindu four-step models for the star-planets approximate the equant suggests that either the equant was transmitted to India and there modified or the equant was modified before transmission to India and the four-step approximation was eventually transmitted to India. If the transmission to India occurred after the *Almagest*, then the greater question becomes how could it happen that the equant, but nothing else in the *Almagest*, was transmitted to India, and this seems a very hard question to

answer with any respectable degree of plausibility. The same line of argument applies, of course, to both the second lunar anomaly, the latitudes of the star-planets, and the true speeds of the planets. In all of these cases, the most straightforward resolution is that many of the things that were conventionally thought to be of Hindu origin because they seemed pre-*Almagest* are in fact pre-*Almagest* and still Greek.

Plant Domestication in India

Charlene Murphy and Dorian Q. Fuller
Institute of Archaeology, University College
London, London, UK

India is believed to possess a unique Neolithic transition toward plant domestication (<http://www.youtube.com/watch?v=FCL0SMbZG6Q&app=desktop>) (Feb 2014 UCL Talk youtube link). It has become increasingly apparent that cultivation preceded sedentary village life in India (Fuller, 2006, p. 52). The beginnings of plant domestication among non-sedentary societies in India have yet to be firmly established as evidence of food production among seasonally mobile societies is difficult to identify in the archaeological record (Fuller, 2006, p. 59). Nevertheless the end of the process, when sedentary villages emerged supported by agriculture, is well established. For most of India this took place around 2500–2000 B.C. It should be noted that this pattern is distinct from that of western Pakistan where preceramic agricultural settlement was established sometime before 6000 B.C., based on crops that had been domesticated earlier in Western Asia, such as wheat and barley (Possehl, 1999, pp. 446–489). Recent archaeological research combined with better botanical documentation of wild crop progenitors in South Asia has provided a basis for postulating several regional foci of plant domestication in India dating to around 3500–3000 B.C.E., based initially on native species.

It has been posited that these foci of plant domestication are mainly located between the savanna and deciduous woodland ecotones which include the South Deccan, Gujarat, and the Western Himalayan foothills, as well as the

Plant Domestication in India, Fig. 1 Map of agricultural origins on the Indian subcontinent. Regions of plausible crop domestication: (1) South Deccan, (2) middle Ganges and/or Vindhyas, (3) upper Mahanadi, (4) foothills of the Indo-Gangetic divide, (5) Saurashtra or southern Aravallis. Zones of early farming Neolithic/Chalcolithic culture areas: (EH) Eastern Early Harappan,

(GN) Ganges Neolithic, (ON) Orissa Neolithic, (SC) Sorath Chalcolithic and Banas culture, (NDC) North Decan Chalcolithic, (SN) Southern Neolithic. The semiarid savanna habitats zone is indicated: this zone and adjacent woodlands were important for most millet and pulse domestications

P

Ganges basin (Fig. 1 Fuller, 2006, 2011, 2013, p. 5). The Deccan plateau of South India, a large arid region featuring rich Neolithic period remains, has only recently entered our awareness as a possible center of agricultural origins (Fuller, 2002; Fuller & Korisettar, 2004; Fuller, Boivin, & Korisettar, 2007) (see also Balter, 2007; Bellwood, 2005). This is largely due to recent archaeobotanical sampling which has shown that a number of the earliest staples of the Southern Neolithic were crop domesticates such as horse gram (*Macrotyloma uniflorum*), mung

bean (*Vigna radiata*), and browntop millet (*Brachiaria ramosa*). These are native to the wild flora in the region (Fuller & Korisettar, 2004; Fuller, Asouti, & Purugganan, 2012). Gujarat (the Saurashtra Peninsula) was an early center for the cultivation for additional savanna crops including little millet (*Panicum sumatrense*) and urd bean (*Vigna mungo*). Both Southern India and Gujarat also appear to have cultivated local foxtail grasses (*Setaria* spp.). The Western Himalayan foothills near the Indo-Gangetic divide are poorly documented in terms

of Neolithic cultural remains, but the occurrence of wild progenitors in the region coupled with occurrence of native domesticates on Early Harappan sites suggests that this region may have had a parallel set of crop origins for mung bean, urd bean, and little millet as well as perhaps other millets such as sawa millet (*Echinochloa frumentaceum*) (Fuller, 2006, p. 46). The central Ganges basin has long been regarded as an early center of rice cultivation, along with many cucurbitaceous vegetable crops. Eastern India, around the modern state of Odisha, has also been postulated as a possible focus of early independent rice cultivation and the domestication center of pigeon pea (*Cajanus cajan*) (e.g. Harvey et al., 2006), although evidence that cultivation began here independently of the Ganges Neolithic remains elusive.

The Neolithic faunal resources are dominated by introduced pastoral herds of cattle, sheep, and goats which may indicate an earlier dispersal of mobile pastoral collectors, who may have preceded the development of agricultural economies and later tendencies toward sedentism. There is no firm evidence in the archaeological record for the transition from foraging to farming. Direct archaeobotanical evidence for the processes of initial cultivation and morphological domestication in South Asia is largely lacking at this point.

However, Neolithic deposits do reveal the first evidence of domesticated crops and more intensive sedentary human occupation of the area (Boivin et al., 2008, p. 179). Despite these factors, based upon the archaeobotanical assemblage, it would appear that plant cultivation was independently invented as wild plant species in the local vicinity were brought into cultivation and domesticated locally rather than coming in as introduced crops domesticated elsewhere. Indeed, crops from Southwest Asia and the Indus Valley region do not reach South India until the Neolithic had been well established in the region (Boivin et al., 2008, p. 179). While inspiration through information exchange with distant farmers cannot be excluded, it is clear that local agricultural origins were based on the cultivation and domestication of plants chosen from local wild populations.

The ecological niches of these wild progenitors of the Indian Neolithic varied but in general focused on savanna to deciduous woodland transitions. The wild progenitor of mung bean (*Vigna radiata*) is known to have occurred in the wet and dry deciduous forests on the eastern edge of the Western Ghats in clearings and along the forest edge and sporadically in the Eastern Ghats as well, as the core area of this region of this area was too dry, even in the past, for wild mung beans (Boivin et al., 2008, p. 182; Fuller, 2006, p. 50). Urd (*Vigna mungo*) is distributed in the moist deciduous forests of the northernmost Western Ghats and Western Himalayan foothills of southern Aravallis, Mount Abu in Rajasthan, and eastern Satpura ranges. Urd is absent from the Southern Neolithic until its very latest stages and the most likely zone of domestication was to the northwest in Gujarat or Rajasthan. Wild horse gram (*Macrotyloma uniflorum*) is native to the Acacia thickets ranging from the Aravalli hills in Rajasthan through the savanna zone of the Southern Peninsula. The wild forms of millets, like *Brachiaria ramosa* of the Southern Neolithic, would have also been sporadic patches within the savanna zone as slightly wetter environments like breaks in slope or the distal edges of ponds (Fig. 2). *Brachiaria ramosa* in particular is of interest as it was overlooked in early archaeobotanical and ethnobotanical research but is now evident as having been a widespread cereal crop in Indian prehistory, especially on the Peninsula (Kingwell-Banham & Fuller, 2014). Thus, with the expansion of savanna and a more restrictive dry season as climates dried from 3500 to 2000 B.C., the mung beans of moist woodlands and the wild millets would have become scarcer. Wild horse gram too likely retreated as grasslands expanded. Taken together there were limited watering holes which encouraged the creation of pulse and millet gardens (Fuller et al., 2014).

Thus, these wild progenitors span both the tropical wet to dry deciduous forests on the hills of the Deccan margins and the drier savanna-woodland zones of the Central Peninsula. This is similar to the more Mediterranean habitat of wild pulses found in the Near East and

Plant Domestication in India, Fig. 2 *Brachiaria ramosa* (Photo by C. Stevens 2014)

the drier steppe habitat of wild barley and wheat. A similar scenario may be imaged in each area in which early mobile collectors were combining plant cultivars from across the adjacent habitats which they frequented in their seasonal hunting and collecting strategy.

The South Indian crop domesticates may initially have been cultivated in shifting fields that suited the more seasonally mobile lifestyle of hunter-gatherer-herders. Herd animals such as cattle, sheep, and goat spread through the savanna of Indus from the Indus region and Baluchistan. It remains unclear the extent to which these livestock spread primarily through adoption by local foragers or dispersed with immigrants and which of these groups was primarily responsible for early pulse-millet farming. Nevertheless, established villages based on these crops and

livestock became increasingly widespread in the Southern Deccan after 2200 B.C. Meanwhile in the Northern Deccan, these crops were taken up alongside introduced West Asian wheat, barley, and pulses, mainly after 2000 B.C.

The processes and motivations for domestication may have been similar in Gujarat. A similar combination monsoon-watered millet and pulse were brought into cultivation probably between 3500 and 2500 B.C. This period saw the expansion of the Thar Desert which would have put pressure on the Mesolithic foragers who had lived within the mid-Holocene green desert and savanna-woodlands to its south. Around 3500 B.C. domesticated cattle were adopted and ceramic production began (Patel, 2008). Clear evidence for cultivation derived from later sedentary sites during the Harappan era (from 2600 B.C.), by which time native domesticated crops were well established and dominated the diet (Weber, 1991; Fuller, 2011).

In the Ganges valley, wild rice would have been an important food resource and one which was increasingly managed over the course of the Holocene, eventually providing the genetic background of domesticated *Oryza sativa* subsp. *indica* (Fuller, Allaby, & Stevens, 2010; Fuller & Qin, 2009). Rice is ubiquitous on all archaeobotanically sampled sites of Mesolithic, Neolithic, or Chalcolithic age (Fuller, 2011). The balance of archaeobotanical and genetic evidence suggests a distinct origin of cultivation of ancestral *indica* rice in this region but that full domestication in the morphological sense was not completed until domesticated *japonica* varieties were introduced to North India from China, allowing for hybridization (Fuller, Allaby, & Stevens, 2010; Fuller & Qin, 2009). This can be understood through a “proto-*indica*” model in which abundant and productive annual wild rice (*Oryza nivara*) was harvested and managed in non-intensive way that did not lead to the evolution of domestication traits. Domestication traits were subsequently hybridized into South Asia rices, perhaps first in northern Pakistan, around or after 2000 B.C., with the introduction of highly developed domesticated subspecies *japonica* rice from China that had been exchanged with other

crops westward through Central Asia. Between 2000 and 1600 B.C., fully domesticated rice is evident from Ganges Neolithic sites, such as Mahagara, alongside adopted wheat, barley, lentils, and livestock that had come from the Indus region. At this time, with this mixed economy, agricultural villages of the Ganges Neolithic grew and proliferated. There is also some evidence that some small millets may have been cultivated in the Ganges, including a native fox-tail (Saraswat, 2004, SENUWAR). Among the many native cucurbits, only ivy gourd (*Coccinia indica*) has an early archaeobotanical record. In contrast to Gujarat, South India or West Asia, early Ganges cultivation focused largely or even exclusively on rice, although the Neolithic becomes more widespread as population grows and mixed cropping is adopted. Similar to South India is the rather late emergence of archaeologically visible, widespread, and sedentary agricultural settlement around 4,000 years ago. This points toward more mobile settlement and early cultivation, perhaps a form of shifting agriculture.

Local plant domestication events in India were combined with agricultural dispersals in an interconnected mosaic of cultivation, pastoralism, and sedentism. The Neolithic transition in India is globally among those that emerged in the middle Holocene, with the established sedentary farming village cultures of India mostly evident as the middle to late Holocene transition around 4,000 years ago. The timing of this agricultural emergence is similar to that in parts of Africa and North America, and similar circumstances of grassland expansion and woodland retreat may have been shared (Fuller et al., 2014). This does not, however, preclude the importance of social factors in transition to food production.

Plant Domestication in the Near East

Shahal Abbo¹, Simcha Lev-Yadun² and
Avi Gopher³

¹Hebrew University, Rehovot, Israel

²Haifa University, Oranim, Tivon, Israel

³Tel Aviv University, Tel Aviv, Israel

Human societies have abandoned their aboriginal hunting-gathering lifeway in favor of economies based on food production independently in several world regions, the Near East included. Major components of this move were the domestication of plants and animals. In this entry, we address the key biological and cultural aspects of plant domestication in the Neolithic Near East (12th–7th calibrated millennia before present) and its bearing on the origins of agriculture as a socioeconomic system. The importance of plant domestication as a central component of agriculture in the Near East and the fact that many of the plants domesticated in the Neolithic Near East still play a significant role in the global economy to this day inspired numerous attempts to find out where are the geographic origins of plant domestication, when were they domesticated, what are the underlying biological and cultural mechanisms leading to plant domestication, and how can all this be explained (e.g., Abbo et al. 2012, 2014a, 2014b; Bellewood 2005; Binford, 1968; Childe, 1951; de Candolle, 1885; Fuller, 2007; Harlan, 1992; Lev-Yadun, Gopher & Abbo, 2000; Purugganan & Fuller, 2011; Redman, 1978; Zohary, Hopf & Weiss, 2012).

Modern, systematic studies on the origin of Near Eastern agriculture and plant domestication combining fieldwork in archaeological sites and the analysis of archaeobotanical finds were pioneered by Robert Braidwood in the late 1940s and the 1950s with the exploration of archaeological sites in Syria, Iraq, and Turkey (Braidwood, 1960, 1975). Developments in archaeological and archaeobotanical

methodology and thinking and in botany, genetics, and plant evolution during the past 50 years yielded enormous amounts of data and a massive volume of literature on the subject, and these enable us to draw an evidence-based reconstruction of plant domestication in the Near East.

Near Eastern agriculture is thought to have started with a crop assemblage including cereals and legumes listed in Table 1. The wild progenitors of these crops were identified based on morphological similarity (botanical criteria) and cytological affinity (genetic criteria) (Zohary & Hopf, 1988; Zohary et al., 2012).

Surveying the literature on the subject, one may easily identify the major issues sitting at the crux of the discussion on plant domestication and on which major disagreements exist. These issues include, but are not limited to, questions such as the geography of plant domestication, the time frame and pace of plant domestication, the scope of plant domestication and the coalescence of the founder package, and the question of human intentionality or consciousness concerning plant domestication.

A summary of plant domestication in the Neolithic Near East focused on these issues, and the scholarly opinions about them are shown in Table 2, alongside a selection of their prominent literature sources. Whether framed as bipolar (either-or) questions or otherwise, the processes related to plant (and animal for this matter) domestication were never simple, unifacial, unidirectional dynamics and the adoption of domesticates was not a simple move. It is clear that opting for domesticates and establishing a rural-agricultural system was a long socioeconomic/cultural process (called Neolithization) involving major changes in lifeways and new structural as well as organizational social systems, all based on a change in human perception of both human-world and human-human relationships. In order to provide an account of such a complex scenario, answers to the basic questions listed above are needed, as well as a detailed cultural reconstruction. The scope of this entry does not allow for

Plant Domestication in the Near East, Table 1 The “founder crops” of the Near Eastern agriculture, after Zohary and Hopf (2000)

Common name	Scientific name	Wild progenitor
Einkorn wheat	<i>Triticum monococcum</i> L.	<i>T. monococcum</i> ssp. <i>boeoticum</i> (Boiss.) A. et D. Löve.
Emmer wheat	<i>Triticum turgidum</i> ssp. <i>dicoccum</i> (Schränk) Thell.	<i>T. turgidum</i> ssp. <i>dicoccoides</i> (Körn.) Thell.
Common barley	<i>Hordeum vulgare</i> L.	<i>H. spontaneum</i> C. Koch
Pea	<i>Pisum sativum</i> L.	<i>P. humile</i> Boiss. et Noë
Lentil	<i>Lens culinaris</i> Medikus	<i>L. orientalis</i> (Boiss.) Handel-Mazzetti
Chickpea	<i>Cicer arietinum</i> L.	<i>C. reticulatum</i> Ladiz.
Bitter vetch	<i>Vicia ervilia</i> (L.) Willd.	<i>V. ervilia</i> (L.) Willd.
Flax	<i>Linum usitatissimum</i> L.	<i>L. usitatissimum</i> ssp. <i>bienne</i> Mill.

Plant Domestication in the Near East, Table 2 A selection of bipolar axes concerning the domestication of plants in the Neolithic Near East and prevalent proponents of each

Geography of plant domestication: The origin of Near Eastern plant domestication was either a highly localized cultural phenomenon or a geographically diffused event sprouting in multiple centers	<i>Highly localized event</i> – Heun et al., 1997; Lev-Yadun et al., 2000; Salamini et al., 2002; Ozkan et al., 2005, Kilian et al. 2009, Abbo et al., 2010a; Gopher et al., 2013
<i>Diffused series of events</i> – Willcox, 2005; Weiss et al., 2006	
Time frame and pace of plant domestication: The domestication of the main Near Eastern crops was a singular, fast (punctuated) move (episode) or a protracted, slow, gradual process unfolding through repeated (multiple) processes/events	<i>Single occurrence</i> – Lev-Yadun et al., 2000; Gopher et al., 2001
<i>Repeatedly recurring processes</i> – Willcox, 2005; Allaby et al., 2008	
<i>Slow and gradual</i> – Tanno & Willcox, 2006; Allaby et al., 2008; Purugganan & Fuller, 2011	<i>Fast changing</i> – Ladizinsky, 1987; Hillman & Davies, 1990; Abbo et al., 2011a <i>Inclusive</i> – Abbo et al., 2010b
Scope of plant domestication and the coalescence of the package: The scale of domestication was an inclusive act of deployment involving most crop plants together or an exclusive act by which domestication of each and every species has occurred independently	
<i>Exclusive, each species selected independently</i> – Willcox, 2005	
Human intention in plant domestication: The process of domestication as a whole was a conscious knowledge-based effort to select and manipulate the various plant species that were eventually transformed or was a product of an unconscious dynamics and natural selection occurring inadvertently either in cultivated fields or via aboriginal resource management operations often perceived as a private case of niche construction similar to adoption of fungi by termites or ants	<i>Intentional, conscious</i> – Ladizinsky, 1987; Abbo et al., 2005; Kerem et al., 2007; Abbo et al., 2009; Abbo et al., 2010b; Tzarfati et al., 2013; Abbo et al., 2014a
<i>Unintentional, unconscious, incident</i> – Harlan et al., 1973; Zohary, 2004; Purugganan & Fuller, 2011	

a detailed discussion; hence, it is focused on the abovementioned aspects.

The Geography of Plant Domestication

To address the geography of plant domestication, evidence from three major independent fields is required: (1) the geobotany and genetics of the living plants, (2) ^{14}C -dated archaeobotanical remains from relevant archaeological sites and contexts, and (3) archaeology – the sociocultural milieu. We offer short comments and conclusions on these three aspects based on evidence known as we write.

Geobotany and genetics – All the wild progenitors of the Near Eastern founder crops (Table 1) are elements of the east Mediterranean oak-pistachio woodland and have different ecological affinities. However, there is only one region in southeastern Turkey and northern Syria where the natural distributions of all the progenitors' taxa coincide (Lev-Yadun et al., 2000; Fig. 1). Genetic analyses using DNA markers (e.g., Heun et al., 1997; Kilian et al., 2009; Salamini, Özkan, Brandolini, Schäfer-Pregl & Martin, 2002) have identified the closest wild genetic stocks of domesticated einkorn and emmer wheats in this geographical region, and the wild stock of lentil to nearby environs (Ladizinsky, 1999). In addition, the wild progenitor of domesticated chickpea is known from this area only. No similar work was done with flax, bitter vetch, and pea. As for barley, Morrell and Clegg (2007) suggest that it has more than one geographic origin.

Archaeobotany – The earliest remains of domesticated cereals (and associated legumes) were excavated from archaeological sites within the same region depicted in Fig. 1 (that we termed the core area) in southeastern Turkey and northern Syria as early as ca. 10,500 cal BP or somewhat earlier.

Archaeology – The core area depicted in Fig. 1 was a center of intensive cultural dynamics in the early Neolithic and shows the appearance

of large-scale sites, innovative architectural features, and lithic technology as well as impressive sculpting in stone and a rich array of imagery (symbolic) items, all in the millennium preceding plant domestication. While large-scale sites continue to appear, changes and innovations in architectural design, lithic technology, clay sculpting, burial customs, and in imagery (symbolic) items take place in tandem with the appearance of domesticated plants ca. 10,500 cal BP or somewhat earlier. Some of these innovative aspects spread later to other parts of the Levant and Cyprus.

At present, there is no evidence-based better alternative than the core area reconstruction (Abbo, Lev-Yadun & Gopher, 2010a; Lev-Yadun et al., 2000). This approach is, however, challenged by authors suggesting multiple, genetically and culturally independent domestication processes (e.g., Brown, Jones, Powell & Allaby, 2009; Fuller et al. 2011; Fuller, Willcox & Allaby, 2012; Riehl, Zeidi & Conard, 2013; Weiss, Kislev & Hartmann, 2006; Willcox, 2005), none of which holds up upon careful evaluation of the botanical, genetic, and archaeological evidence (e.g., Abbo et al., 2010a, 2012; Abbo, Lev-Yadun, Heun, et al., 2013; Abbo, Lev-Yadun, Gopher, 2013; Gopher, Lev-Yadun & Abbo, 2013; Heun, Abbo, Lev-Yadun & Gopher, 2012).

Time Frame and Pace of Plant Domestication

A relatively short time frame for plant domestication was suggested in the past (Hillman & Davies, 1990, 1992, 1999; Zohary, 2004). In recent years an opposing view suggesting a protracted, millennia-long process was advanced (e.g., Allaby, Fuller & Brown, 2008; Purugganan & Fuller, 2011; Tanno & Willcox, 2006). To support the protracted reconstruction, diachronic scatterplots showing gradients in the proportion of domesticated vs. wild cereals

Plant Domestication in the Near East, Fig. 1 The geographic distribution of the seven Neolithic founder crops in the Fertile Crescent (yellow) of the Near East. Large map shows the distribution of wild chickpea (red line) in a core area (green line) within the upper reaches of the Tigris and Euphrates rivers (present-day southeastern Turkey/northern Syria). Neolithic sites are numbered as follows: (1) Çayönü, (2) Cafer Höyük, (3) Nevalı Çori, (4) Göbekli Tepe, (5) Djade, (6) Jerf el-Ahmar, (7) Tell Mureybet, (8) Tell Abu-Hureyra, (9) Hallan Çemi Tepesi, (10) Qermez Dere, (11) Mlefaat, (12), Tell Aswad,

(13) Yiftahel, and (14) Jericho. Inset maps show the natural distribution of the wild progenitors of the founder cereal crops; einkorn wheat (cross indicates the putative site of its domestication), emmer wheat, and barley, and founder legumes (lentil, pea, bitter vetch). The blue lines in the distribution maps indicate the area of the identified wild genetic stocks of the domesticated forms, while the red lines indicate the distribution of the wild progenitors beyond that of the founder stocks (Reproduced with permission from Lev-Yadun et al., 2000, *Science* 288, 1602–1603)

remains in various Neolithic sites across the Near East and similarly scatterplots showing increase in seed size of cereals and legumes were presented. In addition, it was hypothesized that

due to the increased workload associated with non-brittle (domesticated) spike phenotypes of wheat and barley, the Neolithic farmers may have selected against the domesticated

morphology, thereby extending the process of domestication over millennia (Fuller, Allaby & Stevens, 2010).

The major underlying assumptions of a protracted scenario are weak from a population genetics perspective (Heun et al., 2012) as well as from ecological, evolutionary, genetic, and cultural perspectives (Abbo et al. 2012, 2013, 2014a, b). In addition, controlled cultivation experiments with wild and domesticated pea (Abbo et al., 2011b) have reaffirmed Ladizinsky's, (1987) hypothesis that domestication of Near Eastern grain legumes cannot be discussed in the context of long-term (protracted) cultivation. Similarly, recent controlled threshing experiments of wild and domesticated wheat (Tzarfati et al., 2013) refuted Fuller et al.'s (2010) workload hypothesis. Thus, when considered together, the available evidence suggests a relatively short domestication episode.

Scope of Plant Domestication

Classical studies suggested that Near Eastern agriculture arose as a crop assemblage (Helbaek, 1959; Zohary & Hopf, 1988; Zohary et al., 2012). This view is based on the archaeobotany of the relevant sites but has agro-economic and economical foundations too (Abbo et al., 2010b). In recent years, various authors suggested that single, different crops were domesticated in isolation (i.e., independently) by different Neolithic communities that relied on additional wild resources for their dietary and other economic needs (e.g., Willcox, 2005, 2012; Weiss et al., 2006).

Taking into account that in ancient times yield stability was more important than yield maximization, and the biology of the founder crops, it was suggested that the Near Eastern crop assemblage was chosen to function within the east Mediterranean climatic regime and precipitation range, in which good rainy years create the “normal surplus” that sustains farming communities during drought years. This was possible because the three cereals provide a maturity gradient (with barley, emmer, and einkorn being early,

middle, and late, respectively), similarly with pea, lentil, and chickpea (Abbo et al., 2010b). In addition, these legumes and the cereals have a contrasting response to the seasonal rain profiles, and therefore, when cereals provide poor yields, the grain legumes are likely to give high yields and vice versa. Therefore, based on agro-economic and economic considerations, as well as on the available archaeobotanical assemblages from the relevant sites, we favor the crop assemblage concept (Helbaek, 1959; Zohary & Hopf, 1988) rather than the hypothetical model suggesting the domestication of single crops at a time *a la* Willcox, (2005). Similarly, from a nutritional perspective, a mixed diet of both cereals and grain legumes is a more sustainable strategy (Abbo et al., 2009) than reliance on a single cereal or legume.

Human Intention (Consciousness)

Harlan et al. (1973) and Zohary (2004) are probably the most prominent advocates of domestication via the “automatic selection” dynamics viewing the emergence of domesticated crop forms as the result of cultivation regimes operated by early Neolithic farmers in their fields. A whole set of related reconstructions conceptualize plant domestication as occurring in the framework of prey-predator coevolutionary process (Rindos, 1984), via a cultural gradient of indigenous low-level food production strategies (Smith, 2001) or as a private case of niche construction (Smith, 2007, 2011). The common denominator of these models is that they do not attribute an important role to human initiative, choice making, intention, and indeed conscious selection (Abbo et al., 2005, 2011a, 2011b, 2014b).

We hold a different view, based on both published models (Ladizinsky, 1987) and our own field and laboratory experience (Abbo et al., 2011b; Tzarfati et al., 2013). As stated above, there is no justification to see the domestication of the three Near Eastern cereals, neither grain legume domestication as an unconscious process nor their subsequent evolution under

domestication, but rather as an intentional, knowledge-based move.

Conclusions

In assuming that Neolithic cultivators were unable to identify plant types that exhibit better taste or aroma, a more nutritious composition, a non-brittle shaft or axis, free germination, or other notable traits, one is likely to advocate for a protracted domestication process (Purugganan & Fuller, 2011). Under such assumptions, one must allow traits of the domestication syndrome to present themselves to the cultivator in such quantities and frequencies that even our presumably incompetent Neolithic ancestors eventually noticed them. Such reconstructions relying on random mutation events rather than on human initiative indeed make more sense in a framework of geographically scattered domestication episodes of single plant species at a time.

However, when evaluated against the ever increasing hard geobotanical, archaeological, archaeobotanical, and genetic evidence, and based on agronomic and nutritional considerations, plant domestication in the Near East emerges as a single, localized event, a relatively fast move initiated by conscious and capable people who used their ingenuity to domesticate a highly successful package of species – the founder crops – comprising a major part of the world's economy to this very day (Abbo et al. 2010b, 2012, 2014a, b; Zohary et al., 2012). It is important to note that similar independent developments including the domestication of crop packages comprising cereals and legumes have taken place in other world areas thousands of years ago, again introducing what are still some of the most important crops to this very day.

Polycentered History of Science

Jonardon Ganeri

University of Sussex, Falmer, UK

It used to be a commonplace in modernist studies and regrettably remains one still in philosophical historiography that modernity is something that happened first, and uniquely, in Europe. Attempts were made to convert the supposition into a tautology through definitions of modernity that exclude non-European histories and geographies (e.g., in terms of capitalist modes of production, the emergence of nation-states and nationalist collective identities, the industrial

revolution, and secularization). Progress of sorts occurred with the acknowledgment of the existence of alternative regional modernities, but the acknowledgment was tied to a center/periphery model and to an associated ideology of European diffusionism. Shmuel Eisenstadt, for instance, is willing to acknowledge “multiple modernities” but only insofar as these new modernities imitate and copy a first modernity centered in Europe (Eisenstadt, 2000). Postcolonial writers such as R. Radhakrishnan have struggled with what they term “the curse of derivativeness” and have sought to find in the interplay between colonized and colonizer, between tradition and modernity, a more dialectical pattern of engagement, finding, for example, a modernizing effect on Europe in the new modernities of Asia (Radhakrishnan, 2002). I will argue that it is better and more correct to think instead of modernity as a happening potentially indigenous to any culture, irrespective of period or place, that like the Indian banyan tree it is “polycentric,” borrowing here Susan Friedman’s very useful term. “The new geography of modernism,” Friedman says, “needs to locate many centres of modernity across the globe, to focus on the cultural traffic linking them, and to interpret the circuits of reciprocal influence and transformation that take place within highly unequal state relations” (cf. Friedman, 2001, 2006, p. 429). It involves a recognition that these modernities are not derivative but different. Modernity, and this is a point that has been made forcefully by Sanjay Subrahmanyam in his use of the term “conjuncturality,” is also characterized by the “intensification of intercultural contact zones... heightened hybridizations, jarring juxtapositions, and increasingly porous borders both characterize modernity and help bring it into being.” Subrahmanyam says, perfectly accurately, that “modernity is a global conjunctural phenomenon, not a virus that spreads from one place to another” (1998, pp. 99–100).

“Modern science” is one of the more manifest embodiments of modernity, and the above observations have equal application to the history of science. Here, likewise, a center/periphery model ought eventually to make way for a polycentric

For an extended version of this article, see Jonardon Ganeri, “Well-Ordered Science and Indian Epistemic Cultures,” *Isis* 2013, 104: 348–359. Springer thanks the University of Chicago Press for permission to reproduce this abridgement.

understanding, one which acknowledges that scientific practice and scientific modes of inquiry are different if conjuncturally instantiated across the globe. As with modernity in general, the point of departure is to avoid definitions that turn the privileging of Europe into a tautology. In the natural sciences, the standard view is still that a scientific conception of inquiry is a specially European achievement, and the acceptance of that view is what lends continuing significance to a question first posed by Joseph Needham some 40 years ago:

Why did modern science, the mathematization of hypotheses about Nature, with all its implications for advanced technology, take its meteoric rise only in the West at the time of Galileo? ... [The question is] why modern science had not developed in Chinese civilization (or Indian) but only in Europe? (Needham, 1969, p. 16)

Needham, an eminently sympathetic chronicler of the achievements of Chinese intellectual culture, was fully conscious of the fact that “between the first century B.C. and the fifteenth century A.D., Chinese civilization was much more efficient than occidental in applying human natural knowledge to practical human needs,” but he regarded it as uncontroversial that modern science is a uniquely European accomplishment. Needham’s question calls us to ask what Europe had that Asia had not, and there has been a plethora of proposals as to the lacuna, including the Protestant ethic, the application of mathematics in the description of nature, and capitalism’s facilitation of ties between academia and craftsmen (see Cohen, 2011).

If we are to make room for a polycentric history of science, we must begin with a definition that does not presume at the outset that science is in essence an originally European practice. Instead, I will work with a definition that borrows two ideas from recent work in the philosophy of science. The first is Karin Cetina’s idea of “epistemic cultures,” which are “those amalgams of arrangements and mechanisms—which, in a given field, make up how we know what we know ... Epistemic cultures are cultures that create and warrant knowledge, and the premier

knowledge institution throughout the world is, still, science” (Cetina, 1999, p. 1). The second is Philip Kitcher’s idea of science as “a system of public knowledge” (Kitcher, 2001, 2011). Kitcher’s thesis is that what scientific practice should aim for is such public knowledge as would be deemed worthwhile by an ideal conversation *among the whole public* under conditions of mutual engagement. The practice is then, in his phrase, “well-ordered.” It is to Kitcher that we owe the idea that the social values to which scientific endeavor should submit itself are those of a democratic consensus, understood not in the sense of the majority vote but rather in the idea of tutored preferences based on mutual engagement of all human points of view in an ideal conversation. Science, then, in my expanded working definition, is a well-ordered epistemic culture facilitating the production of public knowledge.

Understanding science as a well-ordered system of public knowledge enables us to ask, as Needham could not, whether the epistemic cultures of India or China qualify as genuine modes of scientific inquiry. After describing in a little more detail the role of the idea of well-ordering in the philosophy of science, I will use the remainder of this entry to explore two historical Indian accounts of the ideal conversation whose deliverances seem to govern the aspirations of scientific inquiry. The first is the synthetic pluralism (*syādvāda*) advanced by Jaina thinkers in the second half of the first millennium, and the second is a Buddhist account of balanced deliberation (*vādayutti*) from the time of Aśoka. With a shift in perspective from a center/periphery model of the history of science to a polycentric approach, we can appreciate these contributions as genuine encounters with the emergence of scientific methodologies in India.

Well-Ordered Science

Well-ordered science, another name for which is “properly functioning inquiry” (Kitcher, 2001, p. 118), is science as constrained by goals and values inherent in the pursuit of human goods.

The term “science” here has a broad designation, inclusive of many forms of inquiry that contribute to what Kitcher calls the “system of public knowledge”:

The forms of inquiry designated as “sciences,” where the term is used inclusively to cover studies of art, literature and music, investigations of human behaviour, culture and societies, as well as facets of the physical and organic world, play a central role in our contemporary system of public knowledge, that body of shared information on which people draw in pursuing their own projects. (Kitcher, 2011, p. 114)

A system of public knowledge is defined by norms in the processes of investigation, whose goal is to acknowledge that there is a division of epistemic labor among the contributors to public knowledge, distinguished by their distinctive “trajectories through the habitat” as well as by their various talents and acquired capabilities. Contributors are subject to norms of sincerity and competence with respect to the submissions they make, and there are norms pertaining to submission and transmission. For example, which people are entitled to submit information to the depository and about what? Who is entitled to receive which parts of public knowledge? Fundamentally, there are also norms on investigation, norms that tell us “what types of investigation are viewed as worth pursuing? How are they supposed to proceed? What constraints govern them?” (2001, p. 118, 2011, pp. 85, 90, 91). A properly functioning inquiry, a well-ordered science, is one that proceeds in conformity with these norms, especially the norms on the selection and progress of research agenda.

Kitcher’s radical and distinctive proposal is that the norms bearing on inquiry can be derived from the values and goals of democracy. What the appeal to democracy supplies is a conception of an ideal form of deliberation, inclusive of all perspectives and achieving consensual agreement in matters of significance to all parties concerned. Thus,

Science is well ordered when its specification of the problems to be pursued would be endorsed by an ideal conversation, embodying all human points of view, under conditions of mutual engagement A society practicing scientific

inquiry is well ordered just in case it assigns priorities to lines of investigation through discussions whose conclusions are those that would be reached through deliberation under mutual engagement and which expose the grounds such deliberation would present. (2011, p. 114)

Three ideas are involved in this definition: that of a human point of view, that of mutual engagement in a panhuman conversation, and that of endorsement. Kitcher lacks any general theory of human points of view, their range and variety, of the sort that would ensure that no type of human point of view is left out of the ideal conversation. Mutual engagement, however, is central to his understanding of the account as involving an appeal to democracy more plausible and sophisticated than the “vulgar democracy” of the majority vote which leads only to a “tyranny of the ignorant”. Instead, a mutual engagement requires participants to move beyond their prudential initial preferences in a process of learning about the merits of other points of view and weaknesses of their own, and adjusting their preferences accordingly:

Built into the ideal of discussion under mutual engagement are cognitive and affective constraints: instead of myopic voters choosing in ignorance of the possibilities, and of the consequences for others, completely absorbed in their own self-directed wishes, the ideal conversationalists are to have a wide understanding of the various lines of research, what they might accomplish, how various findings would affect others, how those others adjust their starting preferences, and the conversationalists are dedicated to promoting the wishes other participants eventually form. (2011, p. 186)

What mutual engagement issues in is what Kitcher calls the “tutoring” of the participants, their coming to acquire an understanding of various fields of inquiry, their own preferences revised by a new appreciation of the perspectives of others and by a wish to accommodate others’ preferences as far as possible.

Human Points of View and the Logic of Consensus

This image of the nature of science provides us with a new perspective from which to understand key elements in the philosophical project of Jaina

thinkers in the seventh, eighth, and ninth centuries CE. Situating the Jaina theory in this context will enable us to ask if the extra-European perspective they afford on the concept will itself – in the spirit of mutual engagement – lead to a reformation of contemporary understandings of the requirements of deliberative democracy. For Jaina theory seems exceptionally well targeted on two of the key constituents in Kitcher's depiction of the ideal conversation. These are the classification of all human points of view and the representation of end states of the deliberative process – insofar as it provides extensive and detailed descriptions of any possible human point of view (*naya*) as well as a seven-dimensional structuring of consensual outcomes (*saptabhaṅgī*). These two analyses are jointly constitutive of the celebrated perspectival Jaina theory of conditionality (*syādvāda*).

The Jaina classificatory scheme of human standpoints has it that there is an exact number of distinguishable types. Several interpretations are available in the recent literature (e.g., Balcerowicz, 2001; Ganeri, 2001a, pp. 134–7). In the last section, I pointed to a lacuna in Kitcher's account that he provides no theoretical model that can ensure that *all* human points of view have been taken into consideration in the ideal conversation. The question for any interpretation of the Jaina classification, therefore, if it is brought to bear in the project of understanding how scientific inquiry is constrained by democratic values, is the question of comprehensiveness. Where is the guarantee that excludes the possibility of a human point of view which falls outside the classification? I find this question most fully appreciated in the thinker Malliṣeṇa, who quotes his predecessor Siddharṣigani:

Each preceding viewpoint has larger domain, whereas each subsequent [viewpoint] has [its] province [more and more] determined. The comprehensive [viewpoint] is more extensive in [its] province from the collective [viewpoint], which has as [its] province merely the existent, insofar as it has as [its] scope existence and non-existence. The collective [viewpoint] is larger from the empirical [viewpoint], which reveals an existent [particular] individual, insofar as it shows the amassment (sc. set) of all existent [individuals].

The empirical [viewpoint] has broader reference than the direct [viewpoint], which has as [its] province [only] the present [time], insofar as it rests on the province [made up of] the three times. The direct [viewpoint] has wider reference than the verbal [viewpoint], which shows different things by [reference to] the difference in tense (lit. time), etc., insofar as it comprehends what is contrary to that [scope of the verbal viewpoint]. The verbal [viewpoint] has more comprehensive province than the etymological [viewpoint], which takes separate synonymous expressions as [characterised by] difference of reference (denotata / meaning), insofar as it pertains to what is contrary to that [scope of the etymological viewpoint]. The etymological [viewpoint] has wider domain than the factual [viewpoint], which asserts that an object is different as [something possessed of its] specific activity. Likewise the account [based on] viewpoints, [when] it functions with regard to its province, follows the method of the seven-fold predication of affirmation and negation. (1933, pp. 167.9–18)

It is clear that each of these descriptions relates to a point of view in principle accessible to a human being. There is no mention of anything like a “god's eye” point of view, that is, of a perspective inaccessible to an actual person situated in space and time, following a spatiotemporal path and with restricted perceptual, inferential, and linguistic capacities. It is exactly because of this that the Jaina theory engages with the notion of an ideal conversation in which all human points of view are represented, forgoing any appeal to the transcendental in favor of ideal democratic consensus.

Outcomes of the Ideal Conversation

Kitcher claims that we should recognize three sorts of outcome in ideal conversation: consensus, partially overlapping consensus but agreement on a view as the fair representation of different points of view, and nonoverlapping agreement among the preferences of the participants (2001, pp. 121–2), with majority voting as the course of last resort in the final case.

Conversation may end in one of three states. The best outcome is for the deliberators to reach a plan all perceive as best... Second best is for each person to specify a set of plans he considers

acceptable and for the intersection of these sets to be nonempty. . . . The third option occurs when there is no plan acceptable to all and when the choice is made by majority vote. This is a last resort for expressing the collective will. (cf. 2001, pp. 119–22, 2011, p. 115)

The Jainas whose work I am reviewing add detail and complexity to this analysis. A tripartite scheme arises on the assumption that each participant in an ideal conversation, inhabiting a particular point of view, gives his assent to one range of proposals and dissents from another range. Then we can distinguish the three possibilities identified by Kitcher, that every proposal assented to in any point of view is assented to in any other point of view, that some proposal is assented to from every point of view, and that no proposal is assented to from every point of view. I have elsewhere shown that the Jaina analysis sophisticates this story by introducing the concept of a proposal about which the participant is agnostic, neither giving their agreement nor presenting an objection (see Ganeri, 2002). We might also call such a person tolerant or liberal in their attitude toward the proposal in question, allowing its validity in the conversation without subscribing to it themselves. When the existence of attitudes of toleration, over and above those of assent and disagreement, is introduced into the frame, then possible outcomes multiply, and it is not hard to demonstrate that there is an isomorphism between such possibilities and the seven-dimensional structuring of consensual outcomes (*saptabhaṅgī*) presented in Jaina theoretical discussion (see Ganeri). We might understand the underlying point of this maneuver as follows. Classifying someone's attitude as being one of disagreement forecloses possibilities for compromise and so restricts the opportunities for agreement. What the Jaina theory permits is a more finely grained distinction in the ways that a person might withhold their assent, the distinction between disagreement and toleration. That opens a new range for reaching compromise without unanimous endorsement and so reduces the eventual appeal to the last resort of the majority vote. Understood as a mapping of outcomes in ideal conversation, it is clear that there is no

rejection of the law of contradiction in the Jaina theory (contra Priest, 2008).

The strategy, it might be thought, is especially available under conditions of mutual engagement, when, as a result of sensitive reflection on the priorities and obligations of others, a participant allows space not to be obstructive while not being willing to give his unqualified consent. Yet I do not find an analogue of the idea of mutual engagement in Jaina discussion of the topic, where the presumption seems to be that dialogical positions are fixed and inflexible. For a full appreciation of the virtues of mutual engagement in formulating the deliberative democratic constraints on a well-ordered science, I suggest that we need to look to Buddhist rather than Jaina resources.

Tutoring and Mutual Engagement

Kitcher has this to say about the important notion of tutoring:

In a well-ordered science, a proper verdict would be one achieved by ideal deliberators, well tutored and mutually engaged, who considered the effects both of the proposed experiments and of not undertaking them. . . . Ideal conversationalists form their sympathetic desires by extending mirroring of the desires of others, achieving the desires they judge to be the best balance among the varying assessments (indefinitely iterated) made by fellow participants. If there is complete agreement about how the balancing is to be done, there is no need for further conversation. If there is not, the ideal conversation consists in attempts to support or reject various ways of balancing. (2011, p. 132)

Tutoring involves a revision in one's initial preferences in the light of one's deliberative engagement with others, an appreciation of the virtues of their point of view, and of their perceptions of failings in one's own. It is the idea of a community of suitably tutored participants, rather than raw expressions of self-interest, which distinguishes Kitcher's proposal from the zero-sum rationality of commonplace economic theory. Again, however, I find an absence of depth in Kitcher's description of the phenomenon, and I see in Buddhist Abhidharma a more sophisticated appreciation of the idea in question.

A Buddhist treatise from the third century BCE, the *Kathāvatthu* or *Points of Controversy*, describes for the benefit of adherents to various Buddhist schisms the proper method to be followed in conducting a critical discussion into an issue of doctrinal conflict (*Kathāvatthu*, 1894, 1897). Recent scholarship has largely focused on the question of the extent to which there is an “anticipation” of results in propositional logic. In fact, however, the text offers a particularly clear example of a work whose richness and interest lie elsewhere than in its anticipation of deductive principles and propositional laws. As a meticulous analysis of the argumentation properly to be used in the course of a dialogue of a specific type, its concern is with the pragmatic account of argument evaluation, the idea that arguments have to be evaluated as good or bad with regard to their contribution toward the goals of the dialogue within which they are embedded. The leading concern of the *Kathāvatthu* is with issues of balance and fairness in the conduct of a dialogue, and it recommends a strategy of argumentation which guarantees that both parties to a point of controversy have their arguments properly weighed and considered. There is an important distinction between the global aim of the dialogue as a whole (to rehearse in an even-handed manner all the considerations that bear upon an issue of dispute, to clarify what is at stake even if no final resolution is achieved) and the local aim of each participant (to advocate the stance they adopt with regard to that issue by supplying arguments for it and attacking the arguments of the other parties). A dialogue conducted in accordance with the prescribed method of the *Kathāvatthu* is called a *vādayutti*. The goal of a *vādayutti* is the “reasoned examination” (*yutti*; Skt. *yukti*) of a controversial point in and through a nonconfrontational dialogue (*vāda*). The dialogue is highly structured and is to be conducted in accordance with a prescribed format of argumentation. There is a given point at issue, for example, whether “a person is known in the sense of a real and ultimate fact,” whether there are such things as ethically good and bad actions, and so on. A dialogue is now divided into either sub-dialogues or “openings.” Each such

“opening” proceeds as an independent dialogue, and each is divided into five stages: the way forward (*anuloma*), the way back (*paṭikamma*), the refutation (*niggaha*), the application (*upanayana*), and the conclusion (*niggamana*). In the way forward, the proponent solicits from the respondent the endorsement of a thesis and then tries to argue against it. In the way back, the respondent turns the tables, soliciting from the proponent the endorsement of the counter-thesis, and then tries to argue against it. In the refutation, the respondent, continuing, seeks to refute the argument that the proponent had advanced against the thesis. The application and conclusion repeat and reaffirm that the proponent’s argument against the respondent’s thesis is unsound, while the respondent’s argument against the proponent’s counter-thesis is sound (see further Ganeri, 2001a).

As such, the *Kathāvatthu* is an excellent analysis of the phenomenon Kitcher describes as “tutoring.” Each participant in the ideal conversation comes to understand clearly the embedded commitments, desirable or otherwise, of their own point of view, and each also comes to understand the virtues of the points of view of others. The notion of *vādayutti* constitutes an exact equivalent of the process of mutual engagement and tutoring that Kitcher identifies as essential to ideal deliberation, and the *Kathāvatthu* provides a theoretical framework for understanding the idea unparalleled in any contemporary discussion of deliberative democracy. It provides too what I suggested is lacking in the Jaina analysis of standpoints, namely, an account of the way by which one revises one’s standpoint in the light of an appreciation of the virtues of the standpoints of others. While Jaina discussion presents standpoints as self-formed and static, the supplementation of Buddhist analysis enables us to appreciate their dynamical aspects. With this supplementation, it seems to me entirely right to use the formal tools of dynamic dialogical logic in the modeling of Indian theoretical analysis (dynamic modeling of the mutual revision of each participant’s standpoint within and as a result of the dialogue along with modeling of outcomes).

Conclusion

In answer to Needham, it was not “modern science” which failed to develop in India or China but rather non-well-ordered science, science as unconstrained by social value and democratic consent. What I have argued is that this is not a deficit in the civilizational histories of these countries, but a virtue.

Potato: Origins and Conservation of Potato Genetic Diversity

Timothy Johns

The Origins and Conservation of Potato Genetic Diversity When the conquistador Francisco Pizarro and his men overran the Inca Empire in the 1530s they stumbled upon the potato, a vegetable with an annual crop value that today far exceeds that of all the gold the Spaniards ever removed from the New World. While the first potatoes that were taken to Europe in 1537 were regarded suspiciously or as just a curiosity, the potato is now the most important tuber crop globally, exceeded only in its contribution to human subsistence by the cereals wheat, rice, and maize.

What global humanity assumed from the Andeans was not just an important nutrient source, but also several millennia of accumulated empirical experimentation through which Amerindian farmers molded wild species of tuber-bearing members of the genus *Solanum* into the domesticated potato. This is a process determined by biological and environmental forces and by the intelligence and cultural traditions of these people in relation to plant biology and ecology. The Andeans made good use of the natural vegetative propagation method of potato plants, and altered it to their own advantage. They chose those tubers that were most favorable, and by

planting the same preferred types year after year maintained their favorable characteristics.

Through time, human selection has resulted in specific changes in the potato plant. In comparing the potato of commerce, *Solanum tuberosum*, with its wild relatives, a botanist might first observe the changes in the length of the underground stems, or stolons, that bear the tubers. These are invariably short in modern cultivars. When wild and primitive plants are pulled up, the stolons are likely to break; tubers from plants with long stolons are more likely to be left in the ground, and less likely to be planted the next year. The result is an unconscious selection for shorter underground stems, and a plant that conveniently produces a mass of easily harvestable tubers close to its base. The typical wild potato is golf ball-sized or smaller. Selection for greater tuber size and plant yield improved the output compared to wild types.

In South America, several thousand different landraces and eight species of potatoes are presently cultivated. Farmers recognize them by differences in color, size, shape, and flavor as well as numerous agronomic traits. Most North American consumers are familiar with two or three colors of potatoes. In the Andes selection by humans has resulted in cultivars in which the skin and flesh color may be black, purple, red, yellow, or white, and spotted combinations of any of these colors. Many wild plants, in order to avoid being eaten by herbivores, produce unpleasant-tasting chemicals. Glycoalkaloids, steroidal nitrogen-containing compounds, are normally found in wild species of potatoes in concentrations high enough to be toxic or potentially fatal to humans or animals. These toxins have posed particular problems for Andean peoples and have been dealt with in various ways, including the selection of genes conferring lower glycoalkaloid content.

Andeans make good use of the knowledge that different potato varieties grow best under different environmental conditions. Even if one type fails due to adverse weather or diseases caused by viral, bacterial, or fungal pathogens, others with specific resistances produce enough tubers to sustain the human population until the next season.

Not surprisingly Andean potatoes are a source of invaluable germplasm from which plant breeders obtain sought after traits such as resistance to frost and disease.

Modern potato fields in the high Andes of Peru and Bolivia exist in the very locale from which wild plants were originally taken (the center of diversity for potatoes) and wild plants, growing around fields, or even within fields, hybridize with cultivated plants. This creates a dynamic situation which produces, from seed, new genetic types. These plants will have valuable traits of the cultivated parent and perhaps valuable traits of the wild parent. Some of them will have a combination of characteristics superior to earlier types; they will often grow as weeds in fields and from them farmers continue to choose new varieties that constantly improve the nature of the cultivars.

Essential to this process of crop evolution is the intimate knowledge farmers have of their potatoes. Andean cultivators recognize clones of potatoes for their various qualities and may grow up to 35 different landraces together in one field. Aymara and Quechua Indians know tubers by name, e.g., *laram imilla* (blue girl), and have detailed taxonomies to describe the multitude of types.

The dynamic situation that created this diversity continues to the present day and is an essential resource both for ensuring human survival in the Andes and for maintaining potato genetic diversity. However, commercial interests which supplant this variation with new high-yielding varieties of potatoes, and introduce modern technologies, are bringing rapid change to the traditional agricultural system in the Andes; it is with alarm that scientists view the loss of potato landraces and the farming systems that guarantee the long-term survival of this crop upon which humankind is heavily dependent.

The conservation of biodiversity of both crop and wild species of plants is of global concern. However, the most obvious beneficiaries of the use of plant genes to produce new pharmaceuticals or improved crops are in the industrialized countries of the world. Fewer of the financial benefits derived from patented products are returned to the countries from which the

germplasm was obtained. More importantly little recognition or compensation is provided to the communities who maintain the essential indigenous knowledge about plant properties. Indeed with economic development the marginalization of indigenous peoples in society is often increased rather than diminished; while indigenous peoples have traditions of conserving natural resources, changing economic conditions force them to adopt practices that are often destructive to their traditional systems.

In addition to the potato, the first peoples of the Americas were the domesticators of numerous crops including tomatoes, maize, and chili peppers. From their knowledge systems humanity learned the use of traditional medicines such as curare and ipecac which have provided valuable pharmaceuticals. Recognition of the true value of the intellectual property of indigenous people is the first step to settle the debt established in 1537; international governments and institutions need to seek in conjunction with these communities means to conserve in situ the valuable resources that are maintained within their cultural traditions.

Precession of the Equinoxes

K. V. Sarma

Madras, Tamilnadu, India

Precession of the equinoxes, which in Indian astronomy is called *ayanacalana* (shifting of the solstices), refers to the slow but continuous backward movement of the point of intersection of the ecliptic (which is a fixed circle) and the celestial equator (which keeps on moving backward). This effectively means that the first point of Aries, which is the traditional point of the commencement of the Indian year, is really shifting backward continuously. This shifting is, however, so slow, being a meager 50.2 s per annum, that it comes to be noticed only when it accumulates over several years and takes about 25,800 years to complete one circle.

Such a shift seems to have been noticed in India even during the Vedic times, as is evidenced by the Vedic priests changing the beginning of their year backward, from the constellation Mrgaśiras (Delta Orionis) to the next previous constellation Rohiṇī (Alpha Tauri) and again backward to Krittikā (Eta Tauri) in the course of time. But no measurement of it was made. Precession was not apparent during the time of astronomer Āryabhaṭa (AD 499), since at that time the first point of Aries coincided with the equinox. However, later astronomers noted it and also measured its rate. The first Indian astronomer who gave a rule for finding the value of precession seems to be Devācārya, who, in his *Karaṇaratna*, I.36 (AD 689), gives the rate of precession, which works out to 47 s per annum. The magnitude of the precession, called *ayana-amśa* (degrees of precession), of a celestial body would be the angular distance between its

K. V. Sarma: deceased.

computed longitude and the first point of Aries on the zodiac (which Hindu astronomy takes as fixed).

Hindu astronomers did not conceive the shifting of the equinoxes as a continuously regressing phenomenon, which it really is. They understood it as an oscillatory motion, with the beginning of the Kali era (3102 BCE) as the “zero-precession year,” when the Sun and other planets were at the first point of Aries (Āśvinī), i.e., at the end of Zeta Piscium (Revatī). According to the *Sūryasiddhānta*, an oscillation of amplitude 27° to and fro would take 7,200 years to complete. Thus, during the first 1,800 years, the equinox moved forward by 27°, and during the next 1,800 years, it moved backward, coming back to the zero position at the end of the Kali year 3,600 (which corresponds to AD 499, when Āryabhaṭa composed his work *Āryabhaṭīya*). It will continue to regress for 1,800 years more, till AD 2299, when its forward motion for 1,800 years would commence, again reaching the zero position at the end of 7,200 years, covering, in all, 108°. Certain other texts, such as the *Karaṇaratna* and *Vākya-karaṇa*, take the amplitude of the oscillation as 24°, the period for one complete oscillation being 7,380 years. Among Indian astronomers, it was only Muñjāla (AD 932) who conceived precession as a continuous motion.

Prehistoric Copper Mining in Botswana

Catrien van Waarden
Archaeologist, Francistown, Botswana

Copper has been mined in northeastern Botswana for about 1,200 years with particularly intensive mining during the fifteenth through seventeenth centuries and again in modern times.

Copper chemistry

Element: Cu			
Sulfides: covellite (CuS), chalcocite (Cu ₂ S), chalcopyrite (CuFeS ₂), bornite (2Cu ₂ S·Cu ₃ FeS)			
Oxides: Carbonates, etc.			
Carbonates	Malachite (green)	Cu ₂ CO ₃ (OH) ₂	57.3 % Cu
	Azurite (blue)	Cu ₃ (CO ₃) ₂ (OH) ₂	55.0 % Cu
Oxide	Cuprite (purplish red)	Cu ₂ O	88.8 % Cu
Silicate	Chrysocolla (turquoise)	CuSiO ₃ ·2H ₂ O	37.9 % Cu
Smelting point of carbonates: 700–800 °C			
Melting point of copper: 1,083 °C			
Notes:			
Oxide to copper is like rust to iron			
Sulfides become oxides usually at ground water level			
Prehistoric technology could not smelt copper silicate nor sulfides			
The main copper oxide mined was malachite			
Smelting of malachite: 700–800 °C + reducing agent (carbon from charcoal) + oxygen			
At that temperature, carbon and oxygen produce carbon monoxide (CO), which reacts with malachite to produce copper (solid state):			
Cu ₂ CO ₃ (OH) ₂ + 2CO = 3CO ₂ + H ₂ O + 2Cu			
Copper only melts to liquid at 1,083 °C and can then separate from slag			

Geology

The copper deposits occur in greenstone belts and shear zones of the Zimbabwe Craton. This craton is part of the Archean basement that forms the core of the southern African subcontinent and it stretches across Zimbabwe and northeastern Botswana. Consisting predominantly of granite

and gneiss (c. 75 %), there are also relatively smaller, irregularly shaped areas of metamorphosed volcanic and sedimentary “greenstone” rocks, where hydrothermal fluids coming up through fissures introduced minerals such as copper and gold. Upon cooling, the fluids formed mainly quartz veins on which the metal sulfides precipitated out. A later period of faulting and shearing along the edges of the craton, both within these greenstone belts and the granites, often on contacts, redistributed the minerals and added further enrichment from hydrothermal mineralization. Of the 148 ancient copper workings listed by Summers (1969), all but 16 are found in greenstone belts or shear zone contacts with granite/gneiss. Of these, 59 are located in Botswana and these are the focus here.

Location of the Copper Mines

Summers’ list was drawn up from reports by European prospectors from the 1870s onward for whom the “ancient workings” were important indicators of ore and, with two exceptions, all modern copper prospecting and mining in north-eastern Botswana was initiated by the presence of prehistoric copper mines. Table 1 is an updated list of known prehistoric copper mines in Botswana and their locations are shown in Fig. 1. Apart from the substantial Selkirk Mine, mines in the Tati Greenstone Belt and the Magogaphate Shear Zone were small, but there was a major copper belt between Francistown and the Sua Pan in the Matsitama Greenstone Belt and the Bushman Shear Zone. No ancient workings are known in the rich copper deposits of northwestern Botswana, which were largely covered by Kalahari sands.

Archaeological investigations of the prehistoric copper mines started in the 1990s with impact assessments and mitigation excavations as requirements for modern mine projects. Particularly archaeological mitigations at Thakadu and the Dukwe Mines have increased our knowledge of prehistoric mining and smelting.

The Matsitama Copper Mines

The Matsitama Metasedimentary Group of rocks has a complex history of formation, metamorphism, and deformation, such that the copper mineralization at surface is patchy throughout this large area, which is reflected in the dispersed distribution of small prehistoric mines (Fig. 1; Molyneux and Reinecke 1983).

An exception is the Thakadu Shear System, dominated by a major fold, where copper mineralization is distinctly linear and has been mined by more substantial mines, from southeast to northwest: Thakadu, Peolane, Noko, and Makala Mine, with Logolo and two smaller mines parallel to the north.

Thakadu Mine

Thakadu Mine is at the hinge of the fold, where the sequence of rock formations including the ore zone was folded back on itself. This was mined through, what appeared at surface to be, a double row of pits, overall 180 m long and 10–30 m wide (Fig. 2). After excavation in four pits, Huffman et al. (1995) concluded that these were shafts, but findings at the Dukwe Mines now suggest that they are likely to have been two adjacent, long, narrow open stopes. The other mines west of Thakadu are on the north arm of the fold and consist at surface of a single line of pits, while the south arm is subsurface due to a southward dip and was not mined.

The excavations reached to 3.5–5.75 m into the mine, but it is not known how deep the mine went. The ore was mined away with iron gads and hammerstones, after which the copper oxides, mainly malachite, were cobbled off.

Water Tank Smelting Site

The malachite was smelted in simple pit furnaces away from the mine. A set of four such features was excavated c.130 m from the Noko Mine (Huffman et al. 1995) and the slag analyzed (Eric et al. 1995). They are bowl-shaped pits, 40 × (50–60) cm at surface and dug 25 cm into the pebbly ground with a tuyere port at each end. Tuyeres are trumpet-shaped clay pipes that direct the air from the bellows (itself of wood and/or

leather and not preserved) into the fire. The furnaces were oriented east–west and spaced 1 m apart. They had no superstructure and had become filled with ash, charcoal, tuyere fragments, and slag, while ore, malachite chips, copper wire, some pottery, and animal bones were found in association.

Fayalite-like dendrites in the slag, visible under a scanning electron microscope, indicate that temperatures of 1,200 °C may have been reached in these furnaces, accounting for the presence of almost pure copper beads formed at the melting point of copper (1,083 °C). Some of the copper only reached a semiliquid state, however (Eric et al. 1995).

Four charcoal dates from the mine and two from the furnaces indicate that mining took place in the period c. AD 1480–1670.

Copper Mines in the Bushman Shear Zone

To the northwest of the Matsitama copper belt, a major fault occurred in the granites, visible at surface by a low range of mylonite hills and exposure over about 60 km, trending north-northeast. The associated shear zone includes two relics of metasedimentary rock, which became brecciated and mineralized with copper. In the southern relic are the Phudulooga and Sinti Mines and nearby the Matunga Mine, while in the northern mineralized zone are three large mines, from south to north: the Malokojwe Mine, Dukwe Mine South, and Dukwe Mine North, together referred to as the Dukwe Mines. The three mines consist of a number of features, which when combined are over 700 m long and range in width from 2 to 25 m (Table 1). The ore body was explored underground from 1902 to 1913 by the Bechuanaland Copper Exploration Company, and Malokojwe, then also known as Bushman Mine, was mined from 1914 to 1918. The European miners had encountered prehistoric workings at Malokojwe still at 100' or c. 30 m BS (below surface), going deeper yet, making this the deepest known prehistoric open stope copper mine within the Zimbabwe Craton area.

The Dukwe Mines Project

African Copper Plc was given permission to mine these deposits further through a large open pit which would destroy the three main prehistoric mines, on condition that these would be excavated and documented in detail as mitigation. While major prehistoric copper mines in Zambia, Zimbabwe, and South Africa had already been destroyed by modern mining with little or no documentation, here was a last opportunity to study such a mine complex. This mitigation project has been ongoing in tandem with the deepening of the modern mine, and a number of smelting sites have also been excavated.

The breccias, which host the copper, are largely quartz, calcite, and jasper with varying amounts of graphite; the latter was also mined as pigment to decorate pottery. The ore zone is enveloped in limestone to the east and argillites to the west. Except for presumed surface outcrops of ore, the whole area was covered under a blanket of 1–2 m of black cotton soil, a vertisol, which is loose and crumbly when dry, but sticky when wet. The prehistoric miners removed and dumped this adjacent to the mines along with rock waste, from where it was readily washed back into the mine. As a result the mines were found filled largely with mixed secondary waste deposits with a high black cotton content, with only here and there more packed rock waste that might indicate purposeful back-filling from an adjacent area. Mitigation excavations, therefore, concentrated more on exposing the mine walls rather than analyzing the fill. Excavation of the mines was largely done by backhoe machine with the finer details done manually.

Mining

As the mineralized breccia occurred from surface in elongated lenses with near-vertical dip, the ore was mined through long open stopes (Figs. 4 and 5), although these led also to two underground stopes. Mining was done with iron gads and hammerstones and, where the rock was especially hard, by setting fires and quenching them with water (possibly brought in the pots of which fragments were found in the mines). The long

Prehistoric Copper Mining in Botswana, Fig. 3 Dukwe Mine North, test trench through pit and dump exposed the mine wall and fill

Prehistoric Copper Mining in Botswana, Fig. 4 Dukwe Mine South excavations at 2–5 m below the original surface, viewed from the south

P

stopes were segmented where hard rock with low copper value was left. Backfill and erosion into these segments gave an appearance at surface as shallow pits surrounded by dumps (Fig. 3), similar to Thakadu.

In addition to open stopes and the two underground stopes, there were quite a number of small

prospecting shafts. These were cylindrical, just large enough for one, at most two miners and sunk vertically from surface to depths of 3 to over 5 m BS. They were found especially in areas where the ore seems to have been lost. Where ore was found, this was stoped away and in many cases the main open stope enlarged to incorporate these.

Prehistoric Copper Mining in Botswana, Fig. 5 Plan view of Dukwe Mine South. Brown = surface dumps; blue 2-5 m below surface (BS), green 13-15 m BS, red 25-27 m BS

The Dukwe Mine North is known to have been at least 8.5 m deep, but less than 15 m. For Dukwe Mine South, documentation reached a depth of 27 m and the mine was still deeper, but at 35 m BS recent mining had disturbed the area. Figure 6 is a reconstruction of this mine. At Malokojwe the 35 m BS level is still to be tested, but parts of the mine were encountered at 23.5 m BS.

Volumes of ore mined are still to be determined, but initial estimates are given in Table 2. The ore was sorted in the mine and then cobbled further on the waste heap with hammerstones and only high value copper oxides taken to be smelted.

Smelting and Smithing

Smelting sites were located 0.4–7.4 km from the mines outside the black cotton soil area. These typically were in a clearing in the mopane forest near a water hole, with one or more small houses and a livestock enclosure. Ore preparation, smelting, and smithing took place right in the yard.

Small flakes of malachite were chipped off the ore, probably with a knife, and only this concentrated malachite smelted, so little slag was produced. Smelting was done in pit furnaces like at the Water Tank Site at Matsitama, but smaller and simply dug into the soil, not into a stony

Prehistoric Copper Mining in Botswana, Fig. 6 Model of Dukwe Mine South, viewed from the west. Brown = surface dumps; blue 2-5 m below surface (BS), green 13-15 m BS, red 25-27 m BS

Prehistoric Copper Mining in Botswana, Table 2 Preliminary estimates of ore production

Mine	Number	Stope/pit sizes (m)			Estimated volume (m ³)	Approximate tonnes of ore (volume × 2.8 SG)	Total estimated tonnes of ore
		Length	Width	Known depth			
Malokojwe	1	360	2–25	5 ⁺ –30 ⁺	79,560	222,770	
Dukwe Mine South	1	186	2–14	5 ⁺ –27 ⁺	23,800	66,660	
Dukwe Mine North	1	172	3–10	5 ⁺ –8 ⁺	7,220	20,230	
Sub-total Dukwe Mines							309,600
Matunga	1	75	5–20	3 ⁺	2,700	7,500	
Sinti	7	?				?	
Phudulooga	1	14	15	1 ⁺	210	590	
	1	30	20	4 ⁺	2,400	6,700	
	15	5–10	5–10	1 ⁺ –4 ⁺	2,200	6,200	
Sub-total Phudulooga						13,490	
Sub-total Bushman Shear Zone South							21,000
Total Bushman Shear Zone							330,600
Thakadu	1	180	10–30	5 ⁺	18,000	50,400	
Total Matsitama Greenstone Belt							100,000
Total Matsitama-Bushman SZ copper belt							430,600

Assuming average c. 5 % Cu and 2/3 efficiency in extracting the copper, then 430,600 tonnes of ore would be estimated to have produced 14,353 tonnes of Cu

substratum. These are associated with ash, charcoal or charred wood, sinter with prills of copper, tuyere fragments, and domestic waste. Temperatures reached in these furnaces appear to have been high enough to smelt the ore, but not to melt the copper to liquid and separate it from the slag.

One site had a different type of furnace, made with quartz stones, which had been cracked by fire, and many had become coated on one side with slag. These furnaces had been broken open to remove the copper; hence we do not know the size or shape and we found no pit or burnt area associated. Slag-coated stones were also found on two sites near the Matunga Mine further south and on three sites probably associated with the Selkirk Mine east of Francistown, as well as on sites associated with the Messina

copper mines in the Limpopo Valley in South Africa, where such furnaces had been used in the nineteenth century by Lemba smiths who lived among the Venda (Küsel 1974, p. 247; Stayt 1931, Chapter VI).

These two types are both primary furnaces as both are associated with ore and malachite. The stone furnaces may have reached higher temperatures due to heat retention by the stones, so that copper reached the liquid phase; they may also have produced more copper per smelt. Analysis is ongoing.

No ingots or ingot molds were found, but production specialized in the manufacture of wire by drawing heated copper through successively smaller holes in an iron plate. This was made into bangles of fine wire coiled tightly around a grass or hair core, similar to bangles

made of iron, bronze, and even gold in this region.

Dates

No dates are yet available for the smelting sites and the pottery is insufficiently diagnostic to be certain of the time period. Elsewhere Early Iron Age potsherds (c. ninth century) were found associated with ore, tuyeres, and slag. There is also one site with historic glass beads and bottle glass (c. AD 1900), associated with tuyeres and ore, pottery, and stone tools. Charcoal from the lower levels of a dump of the Dukwe Mine North was dated to c. AD 1300, but there are five dates from in situ charcoal associated with fire setting in the mines from the period c. AD 1480–1670.

Culture-Historical Context

The bulk of the mining in the three large Dukwe Mines and at Thakadu took place when this area was part of the Kalanga State Butua and the capital was at Khami, 100 km to the east near modern Bulawayo in Zimbabwe (Van Waarden 2012). The Malokojwe Ruin on the hills of the Bushman Shear Zone, 12 km south of the Dukwe Mines, may date to this period and was likely the residence of a chief who may have controlled the copper industry.

Much copper as well as bronze was found at Khami, and the Dukwe-Matsitama copper belt was the main source within the state at that time (Summers 1969, p. 112; Van Waarden 2012, pp. 229–233). Copper was traded regionally as wire to make jewelry and even ordinary people were found buried with a bangle or two; bronze bangles were reserved for elite and gold bangles only worn by royalty. This reflected prestige and signaled class distinctions.

Who were the miners? Today the area is inhabited by Khoe (80 %), Kalanga (6 %), and Ngwato (12 %). The latter arrived here in the nineteenth century, but the history of coexistence and trade between Khoe from this area and Kalanga further east probably dates back to the tenth century and continued to the 1980s. Research continues to determine whether Khoe and/or Kalanga mined the copper.

At the end of the seventeenth century, the ruler at Khami was overthrown, the palace burnt down, and the new ruler established the capital 100 km further east at Danangombe, extending the state and including in his sphere of influence the copper mines of central and northern Zimbabwe. This coincides with the end of large scale copper mining in Botswana. It is also possible that the mines had been exhausted of suitable copper oxides and the water table reached.

Analysis of the findings at the Dukwe Mines is still ongoing. Particularly the questions around the two types of furnaces and the ethnic identity of the miners are intriguing.

Acknowledgments Thanks to Dr. Nick Walker for important contributions to the fieldwork at Dukwe Mines, Tapela Chembezi (Afro-Geodata Surveys (Pty) Ltd.) for surveying and Richard MacNeill for modeling Figures 5 and 6, and African Copper Plc for commissioning the Dukwe Mine Project.

Printing and Dyeing in India

Eiluned Edwards

Nottingham Trent University, Nottingham, UK

Defining India

India as we know it today has existed only since 1947; prior to that date, much of South Asia was part of the British Empire and “British India” (1858–1947) included the modern countries of India, Pakistan, and Bangladesh. The Indian Independence Act (1947) integrated territories under direct British rule and the princely states under the suzerainty of the Crown and established the sovereign states of India, Pakistan, and East Pakistan; the latter subsequently became Bangladesh after secession from Pakistan in 1971. Thus, some of the historical discussion that follows refers to the Indian subcontinent as a whole while more recent material refers to modern India only.

Early Textile Production

Indian textile technology, notably the cultivation, processing and weaving of cotton, and the production of fast colors, led the world from at least the second millennium BCE. The first urban civilization in South Asia developed in the Indus Valley between ca.2600 and 1700 BCE and extended over a region that included parts of northwest India and Pakistan. Named Harappan Culture after the site of Harappa in Punjab Province, Pakistan, this early civilization traded with ancient Mesopotamia and Egypt, and among its exports were cotton textiles. In the early twentieth century, archaeologists retrieved reddish-colored cotton fibers that appeared to have been dyed with madder from the site of Mohenjo Daro in Sindh Province, Pakistan (dated 1750 BCE). As madder requires a mordant, this discovery implies that Harappan dyers were familiar with the technology of using metallic salts, such as alum, chrome, iron, tin, and copper, to permanently fix colors to fiber. Pliny provides the earliest description of mordants in use in Egypt in the first century CE and notes that after boiling in a single dye bath, fabric treated with mordants emerges multicolored and with colors that are fast (1957, p. 283). It is almost certain that the technology had transferred to Egypt from India as a result of trade via the Arab Sea.

Beyond these technical accomplishments, Indian artisans came to excel at patterning cloth using colorfast dyes. Their expert manipulation of mordants and a range of natural dyes that included indigo, madder red, and iron paste (which when used in conjunction with tannin oxidizes to produce black) enabled them to produce a wide spectrum of colors and shades. Apart from the simple dyeing of yarns and fabric, they harnessed the technology to decorative techniques, including resist patterning such as tie-dye and batik, as well as hand painting and block printing. The latter technique required coordination of several engraved wooden blocks or stamps to build up a multicolored pattern on cloth using mordant pastes and resist media such as mud, wax, or lime and gum paste.

International Trade

Indian dyers and printers became adept at responding to the demands of a varied clientele and produced patterns for any market, be they for the refined tastes of royal patrons, ceremonial purposes, or everyday use by the general populace. India was a significant entrepôt for early international trade; a log written by a Greek-speaking Egyptian merchant reports on the scale of maritime trade in the first century CE between India and Egypt, listing indigo, cotton cloth, fine cotton garments, silk, and yarn as among the exports from the port of Barygaza (modern Broach) in western India (Casson, 1989, p. 16). By the medieval period, Indian artisans were supplying dyed, painted, and block printed cottons along with other textiles across a vast network that extended from the Mediterranean to Southeast Asia and China via the maritime trade routes of the Indian Ocean and the overland routes of the Silk Road. The main centers for printing and dyeing were in western India and along the Coromandel Coast.

1. The oldest surviving Indian textiles are fragments of dyed, painted, and printed cotton trade cloths that were exported from western India to Egypt. Numerous pieces were retrieved from Fustat near Cairo, a selection of which have been radiocarbon dated to ninth to sixteenth centuries. Several of the fragments from Egypt show remarkable similarities to ninth to sixteenth century Indian textiles found in Southeast Asia, preserved in Toraja, central Sulawesi, as heirloom cloths used for ceremonial purposes (Guy, 1998, p. 51). Indian textiles were central to the exchange mechanisms of the spice trade. The painted and printed cottons that became known as “chintz” (from a northern Indian term *chint* meaning “to sprinkle or spray”) were bartered for much sought-after spices such as cloves, nutmeg, and mace from the Spice Islands of eastern Indonesia and pepper from Sumatra and Java. It was spice that first lured Europeans to India and Southeast Asia in the early seventeenth century; already highly

organized, the trade was dominated by Indian merchants from Gujarat, Arab, and Chinese traders. Initially, the Portuguese, British, and Dutch merchants were unable to break the existing monopoly, but eventually, a triangular trade developed, led by the English and Dutch East India Companies. The Europeans paid bullion for Indian cottons which they then exchanged for spices in Indonesia. It was this mechanism that introduced chintz to Europe. Designs were adapted to suit European tastes, and the multicolored Indian cottons which were light to wear and far easier to launder than the heavy woollens and linens of local production, gradually became all the rage, used extensively for fashion and soft furnishings. By 1664, textiles accounted for three-quarters of the exports from India (Crill, 2008, p. 15). But despite the evident popularity of Indian chintz, by the late eighteenth century, it had been banned in several northern European countries for fear that indigenous woollen, flax, and silk industries were being fatally undermined. The prohibition and the birth of industrialization eventually led to the decline of Indian chintz in Britain, and by the end of the eighteenth century, the trade had all but vanished. Another notable category of piece goods exported by the East India Companies were tie-dyed handkerchiefs or bandanna (from *bandhana*, the Sanskrit for “tying”). They were a popular accessory in Europe, the USA, and the Caribbean, serving as neckties, scarves, and head wraps (Crill & Murphy, 1991, pp. 125–130).

Domestic Market

Indian dyers and printers catered for global and home markets. Domestic products could be as diverse as those for export, covering the needs of the royal courts, temples, and mosques, as well as the mass populace. During the Sultanate period (1206–1526) and the classic period of the Mughal Empire (1526–1857), legions of craftspeople were employed in the imperial workshops, or *karkhanas*, producing textiles, metal work,

wood carvings, and paintings for the their royal patrons and members of the court. An inkling of the glories of Mughal textiles may be gleaned from the *Ain-i-Akbari* which chronicles the reign of the Emperor Akbar (1526–1605) and includes inventories of textiles and garments held in the *toshkhana* or imperial store (Allami, 1989). Mughal period block prints, many of which survive in museum collections in India and the West, were made for use as floor coverings, tent panels, upholstery, coverlets, drapes, hangings, wrappings for the *Quran*, and of course, dress. Stylistically, they reveal a strong Persian influence marked by a preponderance of small floral and botanical motifs repeated over the cloth. Several types of fabrics were printed, including finely woven cottons and silk which might be further enhanced by “tinsel printing” whereby an adhesive paste known as *rogan* was stamped on the fabric to which gold or silver leaf was adhered (Fig. 1). Block printers also

stamped fabrics for the multifarious communities or castes of India and provided domestic textiles such as floor covers and quilts, as well as votive textiles used in private and communal worship. Block prints and tie-dyes played a role, too, in the creation of individual visual identity; the use of particular designs for dress was determined by caste, gender, age, and marital and even economic status (Edwards, 2007, pp. 179–197). Tie-dyed designs were worked on a variety of fabrics, from robust motifs on a rustic veil cloth or skirt of coarse *deshi* (local) wool to minutely worked patterns on blouses and saris of Chinese silk (Fig. 2). Tie-dyed textiles remain an essential item of women’s wedding dress, in red, green, or yellow, which are deemed auspicious; their popularity transcends caste and class. Although caste dress has largely disappeared from urban India, it still prevails in the rural areas where the pattern tie-dyed on a woman’s skirt or printed on a man’s turban cloth pinpoints their membership of

a specific hereditary occupational community (Fig. 3). However, the industrialization of textile production in India (late nineteenth century) and innovations in textile and dyeing technologies such as the introduction of synthetic dyes (late nineteenth century) and screen printing (early twentieth century) undermined the market for tie-dyed and block printed textiles, especially those produced using natural dyes. Popular preference for cheaper, screen printed copies of traditional block prints and tie-dyes meant that by the mid-twentieth century, the original crafts were moribund.

Craft Revival

Determined to establish India as a major force in the new world order that had emerged after the

World War II, Jawaharlal Nehru, the country's first Prime Minister (1947–1963), launched a cultural and economic revival in which the resurrection of Indian craft was to be a key component. Regeneration was initially handled by national agencies including the All India Handicrafts Board (founded 1952), the National Crafts Museum (1956), the National Institute of Design (1961), and state-level craft organizations (1970s onward). Initiatives included a rolling program of exhibition-cum-sales in the cities of India and artisans' participation in cultural festivals overseas (e.g., the *Festival of India* in the USA, 1985–1986) and crucially the development of new products suitable for the urban and overseas markets that were a result of collaborations between professional designers and traditional craftspeople. Although the traditional local market has been overtaken by cheap, mass-produced polyester textiles from the factories of Surat and Mumbai, tie-dyeing and block printing have rallied in some areas. From the 1970s onward, clusters of printers and dyers adapted traditional products and found niche markets for them. The use of natural dyes stabilized although it was not widespread, most printers and dyers preferring the convenience of synthetic dyes. More recently, the spending power of India's burgeoning middle class has seen a sharp rise in the domestic consumption of handmade textiles, especially by urban elites; similarly, the influence of the global "slow fashion" movement and consumer concerns about environmentally friendly production have all served to support the viability of tie-dyeing and block printing.

Centers of Block Printing and Dyeing

Historically, block printing was practiced across the breadth of the subcontinent; tie-dyeing was found primarily in western India, notably Jamnagar and Kachchh district in Gujarat, and Rajasthan; this is still the case. Major block printing centers emerged under the patronage of the Mughals, the British, and the regional courts; of note were Jaipur and environs in Rajasthan,

Printing and Dyeing in India, Fig. 4 Detail of block print at Jaipur, showing typical Rajasthani *buti*

Ahmedabad, Deesa, and Kachchh district in Gujarat, Machilipatnam, and other centers in coastal Andhra Pradesh. Jaipuri production was admired for the variety of its small *buti* (bud) motifs, created by printing mordant pastes of alum and iron, followed by dyeing in madder or alizarin, a technique known as *syahi begar*. Rajasthani block prints have enjoyed a revival since the 1970s, largely down to the commercial success of the Jaipur-based company Anokhi which has played a major role in regenerating the craft (Kumar & Ronald, 2005; Fig. 4). Ahmedabad, long one of the most important commercial hubs of western India, was noted for indigo dyeing and the export of *baftas*, plain-dyed cottons, which appear in profusion in East India Company manifests, and also produced an enormous range of prints for local use as well as

Printing and Dyeing in India, Fig. 5 Detail of contemporary *ajrakh*. Kachchh, Gujarat, 2013

servicing the export market. *Saudagiri* (“trade goods” in Persian) textiles which featured small geometric motifs were exported to Thailand until the outbreak of World War II (Guy, 1998, pp. 150–151). The block prints of Kachchh, Gujarat, were made originally for domestic use and dress by the district’s herders and farmers; latterly, they have been adapted for contemporary urban use as fashion and soft furnishings. At the vanguard of the craft revival movement, the printers of Dhamadka and Ajrakhpur villages are known for block printing using natural dyes, notably for the production of *ajrakh* (derived from *azrak*, “blue” in Arabic), a resist-dyed and mordant-printed textile that is printed on both sides with complex geometric patterns (Fig. 5).

Printing and Dyeing in India, Fig. 6 Detail of contemporary *kalamkari*. Machilipatnam area, 2013

Worn chiefly by Muslim cattle herders in north Kachchh, it is related stylistically and technically to the medieval Indo-Egyptian trade cloths, evidence of which was found at Fustat near Cairo (Edwards, 2011, p. 14). Machilipatnam in south India is one of the few remaining centers for *kalamkari* printing. The term means “pen work” and derives from Persian, reflecting the technical roots of these textiles which were originally drawn and painted rather than printed – a tradition that persists in the temple town of Srikalahasti. Machilipatnam became a production and export hub for printed *kalamkaris*, notably to Persia. The trade had ceased by the twentieth century, but the influence of Persian design is evident in the elaborate florals, arabesques, and prayer niches that distinguish *kalamkari* prints. Refashioned as contemporary products, they have found new markets in urban India and overseas (Fig. 6).

Printing and Dyeing in India, Fig. 7 Chippa printer at work in Bagru, 2012

Hereditary Occupation

Like many occupations in India, especially in the craft sector, dyeing and printing are hereditary professions in India. Caste, a hierarchical system based on occupation and notions of ritual purity and pollution, was outlawed in the Indian Constitution (1950); however, it persists as a daily reality especially in rural India. Traditional knowledge was retained by particular castes, passed down from one generation to the next, and the secrets of dyeing and printing were closely guarded. In Rajasthan and Ahmedabad, printing is dominated by the Chippa caste while indigo dyeing is the domain of Chippa converts to Islam who are known as Rangrez (Figs. 7 and 8). Dyeing and printing in Kachchh, Gujarat, and

Printing and Dyeing in India, Fig. 8 Rangrez indigo dyeing cloth at Bagru, 2012

Printing and Dyeing in India, Fig. 9 Khatri printer at work in Dhamadka, 2013

western Rajasthan is a Khatri occupation; in Gujarat, most of the Khatri artisans are Muslims, while in Rajasthan, they are Hindus (Fig. 9). In contrast to this pattern of hereditary occupation, block printing in Machilipatnam, Andhra Pradesh, is carried out by a caste of former weavers who took up the craft in the 1970's because of the decline of the handloom industry from the nineteenth century onward (Fig. 10).

Dyestuffs and Printing Blocks

Indian dyers were famous for their ability to produce fast blues, reds, and blacks. The classic Indian dyes were derived from plants and minerals, the foremost being indigo (*L. Indigofera*

tinctoria) and madder (*L. Rubia tinctorum*); *chay* (*L. Oldenlandia umbellata*) was an important source of red on the Coromandel Coast. Indigo, which still grows wild in many areas of the sub-continent, was a significant export for nearly two thousand years. From the seventeenth century onward, the British gradually assumed control of the export trade from the Mughals, supplied from the major processing centers at Biana near Agra and Sarkhej in Gujarat. Nowadays, production is much reduced and is limited mainly to south India where the chief sites are Tindivanam, Tamil Nadu, and Vallur district, Andhra Pradesh (Fig. 11). A good deal of contemporary indigo dyeing is actually done with the synthetic form (chemically identical to the real thing) which is widely known as "German indigo" in India,

Printing and Dyeing in India, Fig. 10 Printer at work near Machilipatnam, 2013

Printing and Dyeing in India, Fig. 11 Indigo harvest at Tindivanam, 2007

a legacy of its development and global marketing by the German company, Badische Anilin und Soda Fabrik (BASF), in the early twentieth century. Similarly, madder has been largely replaced by synthetic alizarin (Balfour-Paul, 1998, pp. 81–87).

Printing blocks are customarily made from seasoned hard wood. Formerly, locally grown varieties of teak were used but imported hard woods now supplement local supplies. The wood is cut to approximate size; the surface is planed and sanded by hand until it is perfectly smooth, after which it is painted white; and then, the design is marked out. Blocks are engraved by hand using specialist tools including pre-formed

punches and dies, a bow drill, and small chisels. The number of blocks required is determined by the number of colors and pattern elements featured in a textile design; a complex textile like *ajrakh* requires up to twenty-four individual blocks. Some blocks have a wooden base into which brass or copper strip is hammered to form the outlines of the design, allowing for a finer line to be printed; this type of block is used especially for silk printing. Enclaves of block carvers are used to be found at all the block printing centers, but as that craft has shrunk, they are clustered at Farrukhabad and Pilkhuwa in Uttar Pradesh, Jaipur in Rajasthan, Pethapur in Gujarat, and Pedana in Andhra Pradesh (Fig. 12).

Probability in Non-Western Cultures

C. K. Raju

Centre for Studies in Civilizations, New Delhi, India

Al-Bukhari International University, Alor Setar, Malaysia

The mathematical theory of probability begins with the theory of permutations and combinations, needed to calculate probabilities in games of chance, such as dice or cards. The earliest account of this theory is found in India. This theory is tied to the theory of the Vedic meter (and the theory of Indian music, in general).

The Vedic and post-Vedic composers used combinations of two syllables called *guru* (deep, long) and *laghu* (short). The earliest written account of this theory of meter is in Piṅgala's *Chandaśśūtra* (third c.CE), a book of aphorisms (*śūtra*-s) on the theory of meter (*chanda*). To calculate all possible combinations of these two syllables in a meter containing n syllables, Piṅgala gives the following rule (which explicitly makes use of the symbol for zero) (*Chandaśśūtra*, 1840): “(Place) two when halved;” “when unity is subtracted then (place) zero;” “multiply by two when zero;” “square when halved.” In a worked example, Dutta and Singh (1962) show how this rule leads to the

correct figure of 2^6 possibilities for the Gāyatrī meter with six syllables.

Piṅgala's commentator, the tenth century CE Halayudha, clarifies that this involves the binomial expansion. Thus, in a 3-syllabic meter with two underlying syllables, *guru* and *laghu*, 3 *guru* sounds will occur once, 2 *gurus* and 1 *laghu* will occur twice, as will 1 *guru* and 2 *laghus*, while 3 *laghus* will occur once. Symbolically $(g + l)^3 = g^3 + 3g^2l + 3gl^2 + l^3$. To generalize this to the case of n underlying syllables, Halayudha explains the *meru-prastāra* (pyramidal expansion) scheme for calculation (Bag, 1979), which is identical to "Pascal's" triangle which first appeared in Europe over a thousand years after Piṅgala and about a century before Pascal (on the title page of the *Arithmetic* of Apianus) and in China in the fourteenth century (Needham, 1981). An example, using the Gāyatrī meter is also found in Bhaskara's *Līlāvātī* (Bhaskara, *Līlāvātī*, trans. K. S. Patwardhan, S. A. Naimpally, and S. L. Singh, p. 102. The verse is numbered differently in different manuscripts. K. V. Sarma, in his critical edition of the sixteenth-century southern commentary *Kriyākramakarī* (VVRI, Hoshiarpur, 1975) on the *Līlāvātī*, gives this as verse number 133, while the other cited source has given it as verse number 121). Stock Western histories of mathematics (such as that by Smith, 1958) are unreliable and wrongly state that no attention was paid in India to the theory of permutations and combinations before Bhaskara II (twelfth century CE).

Although this theory of permutations and combinations is built into the Vedic meter, the earliest known written account actually comes from even before Piṅgala and is found in the fourth-century Jain *Bhagvatī Sūtra*. Permutations were called *vikalpa-ganita* (the calculus of alternatives) and combinations *bhanga*. The text works out the number of combinations of n categories taken 2, 3, etc., at a time.

From the earliest Vedic tradition, there is a continuous series of manuscripts linking the first accounts of permutations and combinations with those of Bhaskara II (twelfth century) and later

commentaries on his work up to the sixteenth century CE, such as the *Kriyākramakarī*. (It is these latter texts which arrived in Europe and first brought the mathematical theory of probability to Europe, as detailed later on, through Pascal, Fermat etc.) Thus, (Bag, 1979) the surgeon Suśruta (second century CE) in his compendium (*Suśruta-samhitā*) lists the total number of flavors derived from six flavors taken 1 at a time, 2 at a time, and so on. Likewise, Varāhamihira (sixth century) states the number of perfumes that can be made from 16 substances mixed in 1, 2, 3, and 4 proportions. Similar examples are found in the *Pāṭiganīta* (Slate Arithmetic) of Śrīdhar (tenth century), a widely used elementary school text, as its name suggests, Mahavira's (eighth century) *Gaṇita Sāra Saṃgraha* and Bhaskara II (*Līlāvātī*), etc. Bhaskara mentions that this formula has applications to the theory of meter, to architecture, medicine, and *khaṇḍameru* ("Pascal's triangle"). In these later texts, one finds explicitly stated formulae for permutations and combinations.

For example, to calculate $\binom{n}{r}$ values, Śrīdhar, in his text on slate arithmetic (*Pāṭiganīta*, 1959), gives the following rule.

एकाद्व्युत्तरविधिना रस विन्यासे विलोमतो गुणयेत् ।
पूर्वेण परं क्रमशो रूपादिचयेर्हरेर्विभजेत् ॥

This translates as follows (*Pāṭiganīta*, 72, Eng. p. 58):

Writing down the numbers beginning with 1 and increasing by 1 up to the (given) number of savours in the inverse order, divide them by the numbers beginning with 1 and increasing by 1 in the regular order, and then multiply successively by the preceding (quotient) the succeeding one. (This will give the number of combinations of the savours taken 1, 2, 3, ..., all at a time respectively.) (*Pāṭiganīta* of Śrīdhar, trans. K. S. Shukla. As he points out, similar articulations are found in the *Gaṇita Sāra Saṃgrah* of Mahavira, vi.218, *MahāSiddhānta* of Āryabhaṭa 2, xv, 45–46 etc.).

Thus, in the case of six savours, one writes down the numbers 1–6 in reverse order:

6, 5, 4, 3, 2, 1

These are divided by the numbers in the usual order, to get the quotients:

$$\frac{6}{1}, \frac{5}{2}, \frac{4}{3}, \frac{3}{4}, \frac{2}{5}, \frac{1}{6}.$$

Then, according to the rule, the number of combinations of savors taken 1 at a time, 2 at a time, etc., up to all at a time is, respectively,

$$\frac{6}{1}, \frac{6}{1} \times \frac{5}{2}, \frac{6}{1} \times \frac{5}{2} \times \frac{4}{3}, \text{ etc.}$$

Bhaskara II illustrates these formulae by asking for the total number of five-digit numbers whose digits sum to 13 (*Līlāvātī* of *Bhāskarācārya*, trans. Patwardhan et al., p. 181. They give the number of this verse as 276, whereas, in K. V. Sarma's critical edition of *Kriyakramkarī*, a commentary on the *Līlāvātī*, this is at 269, p. 464).

पंचस्थानस्थितैरंकैर्यद्योगसंख्योदश ।
कतिभेदा भवेत्संख्या यदि वेत्सि निगद्यताम् ॥

Almost all Western histories of probability incorrectly state that the mathematical theory of probability began with a European dispute over gambling in the seventeenth century CE. This account intrinsically lacks credibility because, given that gambling is so ancient, it is hard to understand why a mathematical theory related to it should have developed so late. One readily understands why this happened late in Europe, since Greek and Roman numerals are not suited to anything beyond elementary arithmetic and cannot even represent fractions, and arithmetical skills became widespread in Europe only after elementary Indian arithmetic was first introduced in the Jesuit syllabus ca. 1572.

But mathematics related to games of chance did develop elsewhere. In fact, elementary Indian mathematical texts give us accounts of gambling strategies and methods of calculating gain or loss. The relevance of these weighted averages to gambling was understood. For example, the *Gaṇita Sāra Saṃgraha* (1963) (268.5, 273.5) gives the example of “Dutch bets” mentioned

by Hacking (1975) (Hacking uses the English translation of *Gaṇita Sāra Saṃgraha*, trans. M. Rangacharya (1912), pp. 162–163). This is “a rule to ensure profit (in gambling) regardless of victory or loss,” a method of riskless arbitrage, in short. The text illustrates the rule with an example, where “a great man knowing mantra and medicine sees a cockfight in progress. He talks to the owners of the birds separately in a mysterious way. He tells one that ‘if your bird wins, you give me the amount you bet, and if it loses, I will give you $\frac{2}{3}$ of that amount’”. Then he goes to the owner of the other bird where on those same conditions he promised to pay $\frac{3}{4}$ of the amount. In either case, he earned a profit of only 12 pieces of gold. O mathematician, blessed with speech, tell me how much money did the owner of each bird bet.”

It is also interesting to note that this involves the formula for “mixtures” or weighted averages, exactly the formula used to calculate mathematical expectation (or, say, the expected value of a lottery ticket) in probability theory today. There are other more complicated betting strategies showing that standard Western accounts that the mathematics of gambling began in Europe in the seventeenth century are completely misplaced. That is, when it began in Europe, whereas it began in the world a few thousand years earlier.

Needless to say, the game of dice itself is very ancient in India. The earliest known textual account of gambling is found in the *akṣa sūkta* or hymn on dice in the *R̥gveda* (10.2.34). The long hymn begins by comparing the pleasure of gambling with the pleasure of drinking soma!

There is enjoyment like the soma in those dice
(*R̥gveda*, 10.2.34.1). (सोमस्यैव मोज्ज्वतस्यमद्यो)

It goes on to describe how everyone avoids a gambler, like an old man avoids horses, even his mother and father feign not to recognize him, and he is separated from his loving wife. Many times the gambler resolves to stay away, but each time the fatal attraction of the dice pulls him back. With great enthusiasm he reaches the gambling place, hoping to win, but sometimes he wins and sometimes his opponent does. The dice do not obey the wishes of the gambler, they revolt.

They pierce the heart of the gambler, as easily as an arrow or a knife cuts through the skin, and they goad him on like the ankuṣ, and pierce him like hot irons. When he wins he is as happy as if a son is born, and when he loses, he is as if dead. The 53 dice dance like the sun playing with its rays, they cannot be controlled by the bravest of the brave, and even the king bows before them. They have no hands, but they rise and fall, and men with hands lose to them. The gambler's wife remains frustrated and his son becomes a vagabond. He always spends his night in other places. Anyone who lends him money doubts that he will get it back. The gambler who arrives in the morning on a steed leaves at night without clothes on his back. [Such is the power of dice!] O Dice, I join the ten fingers of my hands and bow to the leader among you!

The mathematics of probability was not restricted to games of chance in India: at a very early stage, it was linked to statistics or sampling theory, used, for example, to count the number of fruits in a tree. The first account of it is found in the Mahabharata epic, traditionally dated to the beginning of the Kali era (–3,102 or about 5,000 years ago). The Mahabharata war, itself, is precipitated when the heroes (Pandava-s) lose their kingdom and dignity during a game of dice (दुत क्रीडा). Yudhishtira, the Pandava leader, who loses the game of dice, realizes that the game is not fair, and says so: निक्तिर्देवनं पापं न चाश्रोत्र पराक्रम (Mbh, Sabhā Parva, 59.5). That is, “Deceitful gambling is sinful, there is no Kshatriya valor in it.” Nevertheless, he continues to play, since he cannot prove the dice are loaded, and, as a Kshatriya, he would be dishonored if he refuses to participate in an enterprise involving risk.

When Yudhishtira is banned to the forest, and ruining his condition, a passing sage consoles him by telling him the romantic story of Nala and Damayanti. Nala, too, loses his kingdom in a deceitful game of dice and loses even his last clothes in a forest where he abandons his wife Damayanti, since he is unable to support her.

Someone advises him to go to R̥tuparṇa, king of Ayodhya, knowledgeable in the science of dice. Accordingly, Nala disguises himself and takes up a job as a charioteer with R̥tuparṇa. Damayanti somehow finds her eventful way home and sends out search parties for Nala. Eventually, she locates him, and to test whether he really is Nala, she announces her second marriage through a *swayamvara* (ceremony to choose a husband). R̥tuparṇa wants to wed Damayanti and rushes to Vidarbha. The distance from Ayodhya to Vidarbha being so large, only an accomplished charioteer like Nala can reach in time, so R̥tuparṇa naturally turns to him.

On the way they stop for a moment under a Vibhīṭaka tree – it is significant that the nuts of this very tree, with five faces, were used in the ancient Indian game of dice (Mahabharata, 1883–1896). R̥tuparṇa cannot resist showing off his knowledge of mathematics and says: the number of fruits in the two branches of the tree is 2,095; count them if you like. Nala wants to know how this was done and threatens to stop and count. He also offers his knowledge of horses in return. Under tight time pressure, R̥tuparṇa succumbs and explains that it is done by counting a portion of one branch. (The story has a happy ending and Nala gets back both his wife and his kingdom). However, what it tells us is that this knowledge of the mathematics of dice, though very ancient, was regarded as valuable and kept a secret to be passed on from one person to another, and not put in common texts.

Lastly, there is the question of continuous probabilities, which are today defined using Kolmogorov's axioms or measure theory. This approach is not really satisfactory since our empirical understanding of probability is based on relative frequency and the so-called law of large numbers. If a coin is tossed 100 times and comes up heads 48 times, the relative frequency of heads is $\frac{48}{100} = 0.48$. On the next 100 tosses, the relative frequency may change to 0.47. However, relative frequency is not the probability, which could be 0.5 if the coin is unbiased. The belief is

that, as the number of coin tosses becomes large, the relative frequency will be closer to the “true” probability. But “closer” in what sense? Suppose, after a 1,000 tosses, the relative frequency is 0.49. Can we be sure that after 2,000 tosses it would not be 0.47? We cannot. In fact, it can even happen that the next 1,000 tosses all result in tails. All we can say (and all that the “law of large numbers” enables us to say) is that it is *unlikely* that this will happen. That is, the probability that this will happen is small. This state of affairs means that empirical relative frequency cannot be used to define axiomatic probability. The issue of the failure of this frequentist interpretation of probability and the way it is resolved by zeroism are taken up in a more advanced article (Raju 2011).

Proofs in Indian Mathematics

M. D. Srinivas

Alleged Absence of Proofs in Indian Mathematics

Most of the scholarly works on history of mathematics assert that Indian Mathematics, whatever its achievements, does not have any sense of logical rigour. For instance, we may cite the following as being typical of the kind of opinions commonly expressed about Indian mathematics:

As our survey indicates, the Hindus were interested in and contributed to the arithmetical and computational activities of mathematics rather than to the deductive patterns. Their name for mathematics was *gaṇita*, which means “the science of calculation”. There is much good procedure and technical facility, but no evidence that they considered proof at all. They had rules, but apparently no logical scruples. Moreover, no general methods or new viewpoints were arrived at in any area of mathematics. (Kline, 1972, p. 190)

While modern scholarship seems to be unanimous in holding the view that Indian mathematics lacks any notion of proof, even a cursory study of the source works that are available in print reveals that Indian mathematicians place much emphasis on providing what they refer to as *upapatti* (proof, demonstration) for everyone of their results and procedures.

Some of these *upapattis* were noted in the early European studies on Indian mathematics in the first half of the nineteenth century. For instance, Colebrooke notes the following in the preface to his widely circulated translation of portions of *Brāhmasphuṭasiddhānta* (ca. AD 628) of ► [Brahmagupta](#), and *Līlāvātī* and *Bījagaṇita* of Bhāskaračārya (ca. AD 1150):

On the subject of demonstrations, it is to be remarked that the Hindu mathematicians proved propositions both algebraically and geometrically:

as is particularly noticed by Bhāskara himself, towards the close of his algebra, where he gives both modes of proof of a remarkable method for the solution of indeterminate problems, which involve a factum of two unknown quantities. (Colebrooke, 1817, p. xvii)

Around the same time, Whish (1835) pointed out that infinite series for π and the trigonometric functions were derived in texts of Indian mathematics much before their discovery in Europe. It would indeed be interesting to find out how the currently prevalent view, that Indian mathematics lacks the notion of proof, obtained currency in the last 100–150 years.

The Tradition of *Upapattis* in Mathematics and Astronomy

A major reason for our lack of comprehension, not only of the Indian notion of proof, but also of the entire methodology of Indian mathematics, is the scant attention paid to the source works so far. Much of the methodological discussion is usually contained in the detailed commentaries, whereas modern scholarship has concentrated almost exclusively on translating and analysing the original works, without paying any heed to the commentaries. Traditionally, the commentaries have played at least as great a role in the exposition of the subject as these original texts.

Among the source works available in print, there are about 25 commentaries which present detailed *upapattis* of results and processes in mathematics and astronomy (see References, Primary Sources). Amongst these, the earliest expositions of *upapattis* are to be found in the *Bhāṣya* of Govindasvāmin (ca. 800) on the *Mahābhāskarīya* of Bhāskarācārya I, and the *Vāsanābhāṣya* of Caturveda Prthūdakasvāmin (ca. 860) on *Brāhmasphuṭasiddhānta* of Brahmagupta. We find a very detailed exposition of *upapattis* in the works of Bhāskarācārya II (ca. 1150): his *Vivaraṇa* on *Śiṣyadhīvṛddhidatantra* of Lalla (ca. 800) and his *Vāsanā* on his own *Bījagaṇita* and *Siddhāntaśiromaṇi*. Bhāskarācārya notes that the exposition of *upapattis* goes back to the

ancient teachers and is handed down by the teaching tradition (Bhāskarācārya II, *Vāsanā* on *Bījagaṇita* 1949, pp. 125–127).

Mathematical Results Should Be Supported by *Upapattis*

The following passage from Kṛṣṇa Daivajña's commentary *Bījapallava* (ca. 1600) on *Bījagaṇita* of Bhāskarācārya, clearly brings out the basic understanding of Indian mathematical tradition that citing any number of instances (even an infinite number of them) where a particular result seems to hold, does not amount to establishing that as a valid result in mathematics. Only when the result is supported by an *upapatti* or a demonstration, can the result be accepted as valid:

How can we state without proof (*upapatti*) that twice the product of two quantities when added or subtracted from the sum of their squares is equal to the square of the sum or difference of those quantities? That it is seen to be so in a few instances is indeed of no consequence. Otherwise, even the statement that four times the product of two quantities is equal to the square of their sum, would have to be accepted as valid. For, that is also seen to be true in some cases. For instance take the numbers 2, 2. Their product is 4, four times which will be 16, which is also the square of their sum 4. Or take the numbers 3, 3. Four times their product is 36, which is also the square of their sum 6. Or take the numbers 4, 4. Their product is 16, which when multiplied by four gives 64, which is also the square of their sum 8. Hence, the fact that a result is seen to be true in some cases is of no consequence, as it is possible that one would come across contrary instances (*vyabhicāra*) also. Hence it is necessary that one would have to provide a proof (*yukti*) for the rule that twice the product of two quantities when added or subtracted from the sum of their squares results in the square of the sum or difference of those quantities. We shall provide the proof (*upapatti*) in the end of the section on *ekavarṇa samīkaraṇa*. (Kṛṣṇa Daivajña, *Bījapallava* 1958, p. 54)

Upapatti for the *Kuṭṭaka* Process

To understand the nature of *upapattis* in Indian mathematics, we have to analyse some of the lengthy demonstrations which are presented for the more complicated results and procedures.

We also have to analyse the sequence in which the results and the demonstrations are arranged to understand the method of exposition and logical sequence of arguments. For instance, we may refer to the demonstration given by Kṛṣṇa Daivajña of the celebrated *kuṭṭaka* procedure, which has been employed by Indian mathematicians at least since the time of ► *Āryabhaṭa* (ca. AD 499), for solving first-order indeterminate equations of the form $(ax + c)/b = y$, where a, b, c are given integers and x, y are to be solved for integers. The *upapatti* is rather lengthy (Kṛṣṇa Daivajña, *Bījapallava* 1958, pp. 85–99; Srinivas, 1987), and we merely recount the essential steps here.

Kṛṣṇa Daivajña first shows that the solutions for x, y do not vary if we factor all three numbers a, b, c by the same common factor. He then shows that if a and b have a common factor, then the above equation will not have a solution unless c is also divisible by the same common factor. Then follows the *upapatti* of the process of finding the greatest common factor of a and b by mutual division, the so-called Euclidean algorithm. He then provides an *upapatti* for the *kuṭṭaka* method of finding the solution by making a series of transformations on the *vallī* (column) of the quotients obtained in the above mutual division, based on a detailed analysis of the various operations in reverse (*vyasta-vidhi*). The last two elements of the *vallī*, at each stage, are shown to be the solutions to the *kuṭṭaka* problem for the successive pairs of remainders (taken in reverse order from the end) which arise in the mutual division of a and b . Finally, Kṛṣṇa Daivajña explains why the procedure differs depending upon whether there are odd or even number of coefficients generated in the above mutual division.

Yuktibhāṣā Proofs of Infinite Series for π and the Trigonometric Functions

One of the most celebrated works in Indian mathematics and astronomy, which is specially devoted to the exposition of *yukti* or proofs, is the Malayalam work *Gaṇita-yuktibhāṣā* or *Yuktibhāṣā* (ca. 1530) of Jyeṣṭhadeva. Jyeṣṭhadeva states that his work closely follows

the renowned astronomical work *Tantrasaṅgraha* (ca. 1500) of Nīlakaṇṭha Somasutvan and is intended to give a detailed exposition of all the mathematics required thereof. The first half of *Yuktibhāṣā* deals with various mathematical topics in seven chapters and the second half deals with all aspects of mathematical astronomy in eight chapters. The mathematical part includes a detailed exposition of proofs for the infinite series and fast converging approximations for π and the trigonometric functions, which were discovered by Mādhava (ca. 1375); it also includes proofs of Brahmagupta's results concerning the diagonals and the area of a cyclic quadrilateral. Some of the proofs in this part have been studied in recent times, after the pioneering work of Rajagopal and his collaborators over 50 years ago (John, 2002; Katz, 1995; Marar, 1940; Paramesvaran, 1998; Rajagopal, 1949; Rajagopal & Aiyar, 1951; Rajagopal & Venkataraman, 1949; Raju, 2001; Saraswati Amma, 1979; Srinivas, 2005). The proofs of *Yuktibhāṣā* have also been expounded in the form of Sanskrit verses (*kārikas*) by Śaṅkara Vāriyar in his commentaries *Kriyākramakarī* (ca. 1535) and *Yuktidīpikā* on Līlāvati and *Tantrasaṅgraha*, respectively.

Upapatti and “Proof”

The Raison D'être Of Upapatti

The notion of *upapatti* is significantly different from the notion of “proof” as understood in the Greek and modern Western traditions of mathematics. The ideal of mathematics in the Greek and modern Western traditions is that of a formal axiomatic deductive system. This ideal of mathematics is intimately linked with another crucial philosophical presupposition that mathematics constitutes a body of infallible eternal truths. It is this quest for securing absolute certainty of mathematical knowledge, which has motivated most of the foundational and philosophical investigations into mathematics and has shaped the course of mathematics in the Western tradition, from the age of Greeks to contemporary times.

Indian epistemological position on the nature and validation of mathematical knowledge is very different from that in the Western tradition. This is brought out for instance by the Indian understanding of what indeed is the purpose or *raison d'être* of an *upapatti*. In the beginning of the *golādhyāya* of *Siddhāntaśiromaṇi*, Bhāskarācārya says (Bhāskarācārya II, 1981, p. 326):

Madhyādyaṃ dyusadāṃ yadatra gaṇitaṃ
tasyopapattiṃ vinā
prauḍhiṃ prauḍhasabhāsu naiti gaṇako
niḥsaṃśayo na svayam
gole sā vimalā karāmalakavat pratyakṣato
drśyate
tasmādasmyupapattibodhavidhaye
golaprabandhodyataḥ

Without the knowledge of *upapattis*, by merely mastering the *gaṇita* (computational procedures) described here, from the *madhyamādhikara* (the first chapter of *Siddhāntaśiromaṇi*) onwards, of the (motion of the) heavenly bodies, a mathematician will not have any value in the scholarly assemblies; without the *upapattis* he himself will not be free of doubt (*niḥsaṃśaya*). Since *upapatti* is clearly perceivable in the (armillary) sphere like a berry in the hand, I therefore begin the *golādhyāya* (section on spherics) to explain the *upapattis*.

Thus, as per the Indian mathematical tradition, the purpose of *upapatti* is mainly (a) to remove confusion and doubts regarding the validity and interpretation of mathematical results and procedures; and (b) to obtain assent in the community of mathematicians. Further, in the Indian tradition, mathematical knowledge is not taken to be different in any “fundamental sense” from that in natural sciences. The valid means for acquiring knowledge in mathematics are the same as in other sciences: *Pratyakṣa* (perception), *Anumāna* (inference), and *Śabda* or *āgama* (authentic tradition).

The Limitations of *Tarka* or Proof by Contradiction

An important feature that distinguishes the *upapattis* of Indian mathematicians is that they

do not generally employ the method of proof by contradiction or *reductio ad absurdum*. Sometimes arguments, which are somewhat similar to proof by contradiction, are employed to show the non-existence of an entity, as may be seen from the following *upapatti* given by Kṛṣṇa Daivajña to show that “a negative number has no square root”:

The square-root can be obtained only for a square. A negative number is not a square. Hence how can we consider its square-root? It might however be argued: ‘Why will a negative number not be a square? Surely it is not a royal fiat’... Agreed. Let it be stated by you who claim that a negative number is a square as to whose square it is; surely Not of a positive number, for the square of a positive number is always positive by the rule... not also of a negative number. Because then also the square will be positive by the rule... This being the case, we do not see any such number whose square becomes negative... (Kṛṣṇa Daivajña, Bṭjapallava 1958, p. 19)

Such arguments, known as *tarka* in Indian logic, are employed only to prove the non-existence of certain entities, but not for proving the existence of an entity, whose existence is not demonstrable (at least in principle) by other direct means of verification.

In rejecting the method of indirect proof as a valid means for establishing existence of an entity whose existence cannot even in principle be established through any direct means of proof, the Indian mathematicians may be seen as adopting what is nowadays referred to as the “constructivist” approach to the issue of mathematical existence. But the Indian philosophers, logicians, etc., do much more than merely disallow certain existence proofs. The general Indian philosophical position is one of eliminating from logical discourse all reference to such *aprasiddha* entities, whose existence is not even in principle accessible to all means of verification (Srinivas, 1986). This appears to be also the position adopted by the Indian mathematicians. It is for this reason that many an “existence theorem” (where all that is proved is that the non-existence of a hypothetical entity is incompatible with the accepted set of postulates) of Greek or modern Western mathematics would

not be considered significant or even meaningful by Indian mathematicians.

Upapatti and “Proof”

We now summarise the classical Indian understanding of the nature and validation of mathematical knowledge:

1. The Indian mathematicians are clear that results in mathematics, even those enunciated in authoritative texts, cannot be accepted as valid unless they are supported by *yukti* or *upapatti*. It is not enough that one has merely observed the validity of a result in a large number of instances.
2. Several commentaries written on the major texts of Indian mathematics and astronomy present *upapattis* for the results and procedures enunciated in the text.
3. The *upapattis* are presented in a sequence proceeding systematically from known or established results to finally arrive at the result to be established.
4. In the Indian mathematical tradition, the *upapattis* mainly serve to remove all ambiguity and doubts and obtain assent for the result among the community of mathematicians.
5. The *upapattis* may involve observation or experimentation. They also depend on the prevailing understanding of the nature of the mathematical objects involved.
6. The method of *tarka* or “proof by contradiction” is used occasionally. But there are no *upapattis* which purport to establish existence of any mathematical object merely on the basis of *tarka* alone.
7. The Indian mathematical tradition did not subscribe to the ideal that *upapattis* should seek to provide irrefutable demonstrations establishing the absolute truth of mathematical results. There was apparently no attempt to present the *upapattis* as a part of a deductive axiomatic system. While Indian mathematics made great strides in the invention and manipulation of symbols in representing mathematical results and in facilitating mathematical processes, there was no attempt at formalisation of mathematics.

The classical Indian understanding of the nature and validation of mathematical knowledge seems to be rooted in the larger epistemological perspective developed by the Nyāya school of Indian logic (Bhattacharya, 1987; Mohanty, 1992). Some of the distinguishing features of Nyāya logic, which are particularly relevant in this context, are:

1. That it is a logic of cognitions (*jñāna*) and not “propositions”.
2. That it has no concept of pure ‘formal validity’ as distinguished from “material truth”.
3. That it does not distinguish necessary and contingent truth or analytical and synthetic truth, that it does not admit, in logical discourse, premises which are known to be false and terms that are non-instantiated.
4. That it does not accord *tarka* or “proof by contradiction”, a status of independent *pramāṇa* or means of knowledge, and so on.

Towards a New Epistemology for Mathematics

Mathematics today, rooted as it is in the modern Western tradition, suffers from serious limitations. First, there is the problem of “foundations” posed by the ideal view of mathematical knowledge as a set of infallible eternal truths. The efforts of mathematicians and philosophers of the West to secure for mathematics the status of indubitable knowledge has not succeeded, and there is a growing feeling that this goal may turn out to be a mirage.

Apart from the problems inherent in the goals set for mathematics, there are also other serious inadequacies in the Western epistemology and philosophy of mathematics. The ideal view of mathematics as a formal deductive system gives rise to serious distortions. Some scholars have argued that this view of mathematics has rendered philosophy of mathematics barren and incapable of providing any understanding of the actual history of mathematics, the logic of mathematical discovery and, in fact, the whole of creative mathematical activity. There is also the growing awareness that the ideal of mathematics

as a formal deductive system has had deleterious consequences on the teaching of mathematics.

Notwithstanding all these critiques, it is not likely that, within the Western philosophical tradition, any radically different epistemology of mathematics will emerge and so the driving force for modern mathematics is likely to continue to be a search for absolute truths and modes of establishing them, in one form or the other. This could lead to “progress” in mathematics, but it would be progress of a rather limited kind.

If there is a major lesson to be learnt from the historical development of mathematics, it is perhaps that the development of mathematics in the Greco-European tradition was seriously impeded by its adherence to the cannon of ideal mathematics as laid down by the Greeks. In fact, it is now clearly recognised that the development of mathematical analysis in the Western tradition became possible only when this ideal was clearly given up during the heydays of the development of “infinitesimal calculus” during sixteenth, seventeenth and eighteenth centuries. As a historian of mathematics notes:

It is somewhat paradoxical that this principal shortcoming of Greek mathematics stemmed directly from its principal virtue – the insistence on absolute logical rigour . . . Although the Greek bequest of deductive rigour is the distinguishing feature of modern mathematics, it is arguable that, had all the succeeding generations also refused to use real numbers and limits until they fully understood them, the calculus might never have been developed and mathematics might now be a dead and forgotten science. (Edwards, 1979, p. 79)

It is of course true that the Greek ideal has gotten reinstated at the heart of mathematics during the last two centuries, but it seems that most of the foundational problems of mathematics can also be perhaps traced to the same development. In this context, study of alternative epistemologies, such as that developed in the Indian tradition of mathematics, could prove to be of great significance for the future of mathematics.

Publishing and Printing in China

Lucille Chia

University of California, Riverside, CA, USA

Printing can be described as a process by which texts and images prepared on a master form are transferred by being impressed onto a receiving surface. Thus, characterized printing is an extremely ancient process that includes the cylindrical seals from the fourth millennium BCE used in Mesopotamia as well as later seals and a wide variety of methods that could produce a three- or two-dimensional impression by inks, dyes, or pigments. Both the master form, prepared in relief or intaglio, and the receiving surface could be made from many different materials. The printed text or image could be used for different purposes – to record information, to disseminate information, to assert authority, to indicate confidentiality, or to convey religious or talismanic power. Printing therefore is not synonymous with publishing or the broadcasting of information. This entry focuses on the technological aspects of woodblock printing (xylography) and traditional movable-type printing (typography), the two methods of printing for publishing that were most important in China until the nineteenth century, when other printing methods, such as lithography and Western typography, were introduced.

Woodblock Printing

The idea for block printing follows easily from using seals to make impressions, a practice known as early as the Shang period (ca. 1500–1050 BCE). The earliest extant seals from the late Zhou (ca. 1050–256 BCE), Qin (221–206 BCE), and Han (206 BCE–220 CE) Dynasties were made of stone, earthenware, metals, or horn and could be used to make impressions on clay, silk, and other surfaces (Tsien, 2004, pp. 57–61). Most of the surviving seals were used to authenticate the identity and

authority of an individual or organization, but there are also some from the first or second century CE that served religious and magical purposes. Textual accounts suggest they were meant to protect occupants of tombs. We also have records about the apotropaic [preventing evil] use of seals carved from peachwood from the first century CE and descriptions of Daoist seals from the fourth century. Buddhist texts, such as one from the fifth century, describe “devil-subduing seals” as well as impressions of the Buddha’s image for devotional purposes. Moreover, the impressions were not necessarily made on silk or paper but on soft clay, sand, or even human skin (Strickmann, 2002). A different application of block printing in China was its use in dyeing textiles, for which we have brass blocks from the second century BCE and one anecdotal account describing a dye-resist method using woodblocks in the eighth century CE (Barrett, 2001).

Equally important for multiple replication of text and image by printing is the availability of a pliant, absorbent surface that could be cheaply produced – paper. Although the earliest extant paper dates to the first or second century BCE (Tsien, 2004, p. 146), historical tradition attributes a Han Dynasty official in the second century CE named Cai Lun with developing high-quality paper suitable for writing and painting.

Although the physical process of block printing may easily be inspired from earlier technologies that applied ink or dye on a given material, they differed sufficiently from the xylographic process so that the latter may not have been immediately obvious as a means of replicating text and image on paper for the purpose of making multiple copies for publication. What was required was a combination of political, religious, or cultural purpose and economic advantage afforded by bringing these techniques together – a vast topic that has received increasing scholarly attention in the last several decades (Brokaw, 2005, 2007; Chia & De Weerd, 2011; McDermott, 2006; Twitchett, 1983).

Woodblock printing developed in China probably by the late seventh century CE and was first used to produce religious materials,

including Buddhist and Daoist scriptures and charms. Although we know of crudely produced woodblock imprints of school primers, “character books” (lists of Chinese characters for students), calendars, and books for fortune-telling from the late ninth century, it was only in the mid-tenth century, just prior to the establishment of the Song Dynasty (960–1279), when the ancient Confucian classics were first printed. In the Song, however, the state, schools, private individuals, and commercial publishers all began to print books, ranging from the Confucian Classics to dictionaries, histories, geographies, medical texts, encyclopedias, collections of anecdotes, school primers, poetry anthologies, plays and ballads, and historical novels. By the beginning of the eleventh century, woodblock printing was a technology that was some 400 years old, so it is no surprise that Song-period imprints should have reached very high level of technical and aesthetic quality. Thereafter, block printing became the dominant printing technology in China, used for producing books, broadsheets, legal and business documents, calendars, pictures, and paper money. By the late seventh to early eighth century, xylography was also introduced into Korea and Japan, where Chinese characters had been adopted for writing these languages. Later on, Korean printing also used movable type, both for Chinese characters and Hangul, the native alphabet devised in the fifteenth century. The Japanese also used both xylography and typography, for Chinese characters and the native *kana* script. In China, it was not until the late nineteenth century when Western technologies, such as lithography and modern movable-type printing, were introduced into China and began replacing xylography. Woodblock printing of books finally died out some time in the first half of the twentieth century, but it is still used as an artistic medium.

The process of woodblock printing is quite simple (Edgren, et al. 1984, pp. 16–21; Tsien, 1985, pp. 196–201; Pietzcker, 2003). The text (and/or picture) is first written or painted by ink brush on a piece of paper. This sheet is then

placed facedown on a previously prepared block of wood and a wet brush is used to rub the ink from the paper to the woodblock. Next, a blockcarver takes the appropriate knives and gouges to carve out the characters and images (Barker, 2005, pp. 26–42; Tsien, 1985, pp. 196–200; Pietzcker, 2003) as well as the frame around the leaf (folio), if there is one. Once the woodblock is carved, a water-based ink is applied, and a blank sheet of paper is pressed down and rubbed against the block to transfer the text onto the sheet. For monochromatic printing, usually the text and image (s) are all carved on one block; for polychromatic printing (Barker, 2005, pp. 48–52; Pietzcker, 2003; Tsien, 1985, pp. 277–292), different blocks are used, each corresponding to a specific color. The complete contents of a sheet require printing off the entire set of blocks, a process that requires careful registration, which could be achieved in different ways, such as using the traditional Chinese printing table (Barker, 2005, pp. 58–60). (We should note that in addition to wood, printing blocks made of bronze were also used, mainly for printing paper money and some official documents, and we have a few extant examples from the Song, the Jurchen Jin (1127–1234), and the Mongol Yuan (1279–1368) Dynasties.)

For monochromatic woodblock printing in particular, with the exception of the time-consuming step of engraving the characters and/or picture on the woodblock, which requires the service of skilled carvers, the rest of the process is quite straightforward. In fact, one of the great advantages of woodblock carving is its simplicity and portability. This may explain why the Chinese and other East Asians who used woodblock printing did not talk of a “printing revolution” in the same way that the Europeans in the mid-fifteenth century did when typography developed or the way writers today talk about a “computer revolution.” In a sense, xylography was a transparent technology – more like photocopying in the ease of its acceptance and widespread use, so that people simply took to using it without the fanfare surrounding other technological revolutions.

Materials and Tools Used in Woodblock Printing

Paper (Tsien, 1985, esp. pp. 42–96; McClure, 1986; Hunter, 1947/1978)

The kinds of paper used in woodblock printing were either the same or similar to those used for handwritten texts and hand-drawn images and for painting and were made from different materials, including fibers of tree barks (mulberry and paper mulberry), bamboo, and basts (hemp, jute, ramie, rattan). Papers composed of mixtures of different fibers were common. The quality of the paper depended not only on the kinds of fiber used but even more on the treatment of the pulp in the many steps of the papermaking process. For example, while untreated bamboo pulp would yield papers with a yellow or tan color, it could be bleached to varying degrees of whiteness. Sizing to control the paper’s absorbency of ink and dyes using various materials (gelatin, gum, gypsum, starch) also was essential. The same pulp could be used to make sheets of different thicknesses. Papers could be dyed either for artistic effect or infused with an insecticidal liquid from the Amur cork tree that gave the sheets a yellow tinge. The quality of papers ranged from very fine – smooth, lustrous, and white – to just adequate for printing but often with a yellow or brown tinge due to the lignin or gray from dirt remaining in the pulp. Many of these different papers had distinct names, which varied from place to place. Table 1 gives a very brief listing of just some of the papers used in block and movable-type printing in imperial China.

Because printing paper for traditional Chinese books and pictures is generally much thinner than that used in Western books, the paper is printed on one side only, and for books, the sheet is then folded in half (see below). Thus, the problem of the text from one leaf showing through another is not significant, even with cheap imprints. The thinness of the book paper does cause problems in taking an impression from the woodblock. Some care must be exercised not to tear the sheet when rubbing the back of it on the inked woodblock, but if the rubbing is too lightly done or the block is worn, the resulting impression will not be sufficiently dark. Yet another problem is

Publishing and Printing in China, Table 1 Chinese papers for printing: a brief sample (fibers of tree barks (mulberry and paper mulberry), bamboo, basts (hemp, jute, ramie, rattan))

Kind of fiber	Kind(s) of paper
Bast	
Hemp (<i>da ma</i> ; <i>Cannabis sativa</i>)	<i>Ma zhi</i>
Rattan (<i>teng</i> ; <i>Calamus rotang</i>)	<i>Youquan zhi</i> , named for Youquan in Hangzhou, Zhejiang province
Jute (<i>huang ma</i> ; <i>Corchorus capsularis</i>)	
Ramie (<i>zhu ma</i> ; <i>Boehmeria nivea</i>)	
Flax (<i>ya ma</i> ; <i>Linum perenne</i>)	
Tree bark	
<i>Tan tree (Pteroceltis tatarinowii)</i>	<i>Xuan zhi</i> : soft, white, fine paper made from the bark of the <i>tan</i> tree and straw; named for Xuancheng, Anhui – for printing and artwork
Paper mulberry (<i>chu</i> or <i>gu</i> or <i>gou</i> ; <i>Broussonetia papyrifera</i>)	<i>Gupi zhi</i> , Guangdu zhi (from Guangdu, Sichuan province)
Mulberry (<i>sang</i> ; <i>Morus alba</i>)	
Bamboo (<i>zhu</i> ; many species and varieties used)	“Cotton paper” (<i>mian zhi</i>) <i>Lianshi zhi</i> Both made from bleached bamboo pulp and/or paper mulberry bark Bamboo paper (<i>zhu zhi</i>); “book paper” (<i>shuji zhi</i>): yellowish, from unbleached bamboo fibers, generally for commercial printing “Document paper” (<i>gongdu zhi</i>): heavy, sturdy paper made of fine bamboo for official documents, but its back sometimes used for printing books

that with age the paper becomes increasingly brittle because of the substantial amount of lignin as well as other chemical changes. The resulting decrease in fold strength is obvious in the many books whose leaves are wholly or partially split along the centerfold, which receives the brunt of handling by the reader. Yet another problem is

that the impressions of mediocre imprints are not black but gray. Although this difficulty is blamed chiefly on the use of poorer inks (see below), the varying ability of different kinds of paper to absorb ink is also a consideration. The same ink may appear more pallid and duller on inferior bamboo paper than it does on better-quality paper.

Ink

Like paper, the ink used for printing was generally of a lower quality than that for calligraphy and painting. Although the making of highly prized ink cakes has been described appreciatively and in great detail and the names of master inkmakers recorded (Tsien, 1985, pp. 240–251), little is known about the production of cheaper inks. Printing ink was most likely made from pine soot (Song, 1637/1966, p. 287), which is cheaper than the lampblack made from various oils (tong, sesame, etc.), and results in an ink with a flat, dark black color. Moreover, since printing ink need only be sufficiently dark and adhere to the paper without smudging but need not fulfill the aesthetic requirements of ink for painting, it was composed of far fewer ingredients. Two descriptions from the eighteenth and early twentieth centuries are quite similar. After being beaten and sifted through a sieve, ten parts of the soot were mixed with one-part cowhide glue and added to water and wine to form a thick paste. To dispel its bad odors and improve its qualities, the paste was stored in a jar for at least three summers. When it was to be used, it was mixed with enough water to make a liquid and strained again. Judging from Chinese block-printed books in general, this ink was adequate for printing. The main noticeable defect, evident in many commercial imprints from all periods, is the pale color – dark gray rather than black – of the impressions, which probably resulted from overdiluting the ink paste with water as a cost-cutting measure.

Cutting Woodblocks

Traditional Chinese woodblocks are made from plankwood (cut along the grain), which, for a given tree trunk, yields larger pieces than the

end-grain wood (cut against the grain) and allows the cutter to avoid the problematic knotty heartwood (Tsien, 1985, pp. 196–201). The unplanned blocks are then seasoned up to several years, until they have dried and shrunk and warped as much as they are likely to. Finally, the blocks are planed, oiled, and polished. The actual process differs from place to place. In one procedure, woodblocks are boiled (to remove the sugar and other substances) and then left to dry. Drying, ideally in a cool, airy place away from light and heat, is the essential step in the seasoning process. Carved blocks should be stored under the same conditions, standing upright, with a slight gap between adjacent blocks to allow the circulation of air. Vertical storage allows moisture and heat to penetrate the two carved surfaces equally and renders a block less liable to mechanical abrasions than if it were lying flat.

Generally, an even, close-grained, and relatively hard wood is preferred because it allows for the cutting of finer lines and more impressions. An extremely hard wood like maple that is very difficult and slow to cut, however, is neither practical nor economical for the quantity of blocks required in book production. The choice of wood also depends on the kind of material being printed (text or pictures) but more often on the availability and cost of the wood. The woods used for block printing in China include camphor, catalpa, boxwood, Chinese honey locust, and fruitwoods such as pear and Chinese date (jujube), as listed in Table 2 below. The Manchurian catalpa was so widely used that the Chinese character (*zi*) acquired a second meaning – woodblock printing. Pearwood is a relatively hard wood and can be used for general-purpose woodblock printing.

Of the various processes required for producing a Chinese woodblock book, the one calling for the most skill is the carving of the characters and images. Thus, the majority of the terms that have come to mean publishing a woodblock imprint refer to the engraving process. These words are also quite fitting since once the woodblocks for a book are carved, they are permanent in a way that movable type composed in a frame is not. For woodblock imprints, the idea of an

Publishing and Printing in China, Table 2 Some Chinese woods for block printing

Kind of wood	Description
Pearwood (<i>li</i> ; <i>Pyrus sinensis</i>)	Medium-hard surface; normal printing block use; used for carving text
Jujube (<i>zao</i> ; <i>Ziziphus vulgaris</i>)	Normal printing block use; harder
Manchurian catalpa (<i>qiu</i> or <i>zi</i> ; <i>Catalpa bungei</i>)	Normal printing block use; very hard, for cutting delicate lines as in pictures for illustration
Little leaf boxwood (<i>huangyang</i> ; <i>Buxus sempervirens</i>)	Also used today; softest, used for carving regular text; now only available in small surfaces
Ginkgo (<i>yinxing</i> ; <i>Ginkgo biloba</i>)	Also used today; more absorbent; excellent for block making
Honey locust (<i>baitao</i> or <i>zaojiamu</i> ; <i>Gleditsia sinensis</i>)	Also used today; very hard, for cutting delicate lines as in pictures for illustration; now only available in small surfaces
Maple/Chinese sweet gum wood (<i>fengmu</i> ; <i>Liquidambar formosana</i>)	Excellent for block making
Manchurian ash (<i>shuiuliu</i> ; <i>Fraxinus mandshurica</i>)	Strong, linear grain

“edition” and its date more properly relates to when the blocks were carved rather than to the date when the impressions were made, which could be at any time after the blocks have been cut. Thus, a work described in library catalogues and bibliographies as a *Song kanben* is printed from blocks carved in the Song. In the absence of any evidence such as repairs that can be dated, materials added subsequently (including owners’ seals), or possibly the printing paper, it would be hard to know when an impression was made from the blocks. In fact, many extant copies of old Chinese books are late impressions made from woodblocks engraved earlier.

The recording of the engravers’ names in an imprint is useful to scholars for several reasons. First, it is possible to date an imprint approximately if the name(s) of engraver(s) match those of another imprint with a known date. Second, in much the same way, the provenance of an imprint may be determined if it has the same group of

carvers as another imprint whose place of origin is known. Finally, by knowing how many different carvers worked on a given text, it is possible to estimate the minimum time required for producing the imprint, since the carving is the slowest step in the overall process. For example, in one set of the Confucian Classics produced in the sixteenth century, each work had over 110 different carvers. Since each carver can cut 100 characters a day, the shortest period that a work with 300 characters per leaf and 200 leaves could be carved would be about 6 days. Actually, the time required was much longer, since the evidence indicates that not all the carvers worked at the same time, and errors in the text had to be corrected.

The technique of carving both text and image on woodblocks changed very little for the thousand or more years that Chinese books have been produced. Block carving is the rate-determining step in the physical production of imprints and probably the costliest in terms of material and labor. Thus, that block printing was never supplanted by another technique for most of the late imperial period shows that it was an economically viable method for commercial book production for all this time. Of the two developments that became widespread in the Ming Dynasty (1368–1644), color printing and the use of the calligraphic style known as craftsman style (*jiangti*), the former was an extension of the potential of woodblock printing and the latter made carving more efficient and allowed more text to be packed onto a page without seeming too cramped or illegible. In fact, these modifications in block-carving techniques can be seen largely as responses to the pressures of a rapidly expanding book market in the mid- and late Ming and even more so into the Qing.

Making Impressions

The number of “acceptable” impressions made of a woodblock varies wildly depending on the source consulted, which almost never specifies the specific wood or paper used. The blurry nature of many cheaper imprints is much more likely due to printing too many copies from a woodblock and/or printing more than

200–300 copies without letting the woodblock “rest” from several hours to a day. Without a pause, the block would swell up as it absorbed the water-based ink and to a lesser extent from the continual rubbing to transfer the impression to the paper. (Printers using wooden movable type had to deal with a similar problem; see Chia, 2002, pp. 30–31.) This was probably a widespread problem among commercial printers anxious to print as many copies of a book as quickly as possible but remains almost unmentioned in the traditional literature on rare books and printing, since presumably such a flaw would not have afflicted the higher-quality books valued by bibliophiles.

The number of satisfactory impressions that can be pulled off a woodblock depends on the hardness of the wood, its water absorbency, weather conditions, and the standards of the printer. According to two modern publishing houses, 2,000–3,000 copies can be made from pearwood blocks before minor repairs need to be made. Actually, the equivalent of a “press run” usually was a much more modest number – between 20 and 200 copies. Since woodblocks lend themselves easily to printing on demand, it made better economic sense not to use ink, paper, and labor producing more copies than can be sold at a given time. An excellent example is the use of blocks in a Buddhist temple’s possession to print one or more copies of a sutra on a donor’s request. Finally, although woodblocks may seem permanent once carved, they are all too subject to the ravages of insects, fire, water, changes in humidity and temperature, as well as damage by humans. Woodblocks are thus far more liable to destruction long before they wear out from too many impressions. At the Rongbao Studio art shop in Beijing today, frequent repairs are made even within 30–50 years, with about 10–20 % of the blocks having to be replaced during that period of time. Finally, a certain amount of care and time is required to obtain clear pages even from new blocks. For example, often in a poor imprint, part of the impression on a sheet would come out quite clearly, whereas another part would be faint or blurred, indicating a problem with either the printing block itself and/or with the impression.

A commercial printshop either in a hurry to beat its competitors to the market with a cheap edition or unable to pay for repairing old blocks or engraving new ones would ignore such considerations and might simply keep making impressions until they were nearly illegible.

Bookbinding (International Dunhuang Project; Martinique, 1983; Tsien, 1985, pp. 227–233)

It is probably safe to say that all the different kinds of bookbinding used for imprints in imperial China had already been used for manuscript works, but those formats that were more convenient for printing grew in popularity with the advent of print (Table 3). Nevertheless, convenience was not always the deciding factor in choosing the format of a printed work. For example, the Buddhist *Kaibao Canon*, compiled and published by the state in the early Song (972–83) and the largest single printed work from the dynasty, was produced in the more traditional scroll format, probably because of the momentous circumstances of the work.

Movable-Type Printing

The Chinese also developed movable-type printing (Edgren et al., 1984, pp. 22–23; Tsien, 1985, pp. 201–222) by the mid-eleventh century at the latest, when Shen Kua, a Song scholar, wrote a vivid description of the process using earthenware type by a craftsman named Bi Sheng. Other materials used for making types of individual Chinese ideographs and other symbols included enamel ware, wood, and various kinds of metal such as bronze and tin. In the late thirteenth century, Wang Zheng described in some detail the procedure by which he produced, organized, and used wooden movable type (Tsien, 1985, esp. pp. 206–207) to print his treatise on agriculture. By the early Ming Dynasty, bronze type was also used by government offices, schools, and private and commercial printers to produce books. During the Qing Dynasty in the early eighteenth century, one of the largest printing projects was that of the huge encyclopedia of 5,020 volumes, *Gujin tushu jicheng* (Compendium of texts and

Publishing and Printing in China, Table 3 Chinese bookbinding formats

Name of binding	Description	Notes
Scroll (<i>juan</i>)	One continuous roll made by pasting together separate sheets	
Whirlwind (<i>xuanfeng zhuang</i>)	A number of sheets, each successive sheet longer, all bound together by paste and a split bamboo rod at one edge	No extant example of printed work in this format
Concertina (<i>jingzhe zhuang</i>)	Sheets pasted together, then each sheet folded	Mainly used for religious works; convenient for reading, as each fold flips very easily
Butterfly (<i>hudie zhuang</i>)	Sheets written/printed only on one side facing in, folded in half, and pasted together	Became popular by Northern Song (10th c. onward)
Backwrapped (<i>baobei zhuang</i>)	Each sheet folded in half, with written/printed sides facing out, sheets attached by paper twists forced into holes on one edge of the sheets	Popular starting in the Song Dynasty (ca. 12th c onward)
String bound (<i>xian zhuang</i>)	Each sheet folded in half, with written/printed sides facing out, sheets sewn together with thread	Popular starting in the mid-Ming Dynasty onward

images old and new), compiled and published by the imperial court at Wuying Hall.

There are, however, a number of reasons why xylography was dominant in China for over a thousand years. First, it was more efficient to carve the contents of an entire leaf on a woodblock than to compose the type for the text with so many different Chinese characters.

Even a simple text may require several thousand different characters, unlike that in an alphabetic language, with only 26 or so letters in lower and upper cases. As Tsien Tsuen-hsuei pointed out (Tsien, 1985, p. 220), a fount of at least 200,000 Chinese types would be required to include enough characters (with 20 or more of the more popular ones of each size). Second, the process of woodblock printing is relatively simple and economical, and printing facilities could be easily set up wherever the materials (paper, ink, wood, brushes) were available or could be produced.

We should not, however, think of woodblock and movable-type printing in China as two entirely separate or competing technologies. Sometimes they were used in combination to produce certain works. For instance, because of the somewhat formulaic nature of texts in family/lineage genealogies that required a relatively limited variety of characters, it was feasible for printers to use movable types for printing them. These texts set in movable type could be placed in a large form together with block-carved images and tables, for example, with drawn portraits of family members and some family tree diagrams (Xu, 2005).

There is no other cylindrical tower known within the great Maya region. Some buildings can be compared in morphology, such as Mayapan's round temples or the cylindrical building at Chichén Itzá, best known as "El Caracol." But there is an elementary difference between them: Puerto Rico's tower has a solid core, and the others have interior spaces and vaults.

Few studies have been carried out at Puerto Rico (Andrews IV in Aveni, 2005, p. 383; Benavides, 1999) and the tower has been mentioned in some other papers (Andrews, 1989; Kelly & Kelly, 1982). But the first archaeological research was carried out by archaeologist Antonio Benavides Castillo (1999). The results on the excavations showed that previous researchers used incomplete data about the morphology of the cylindrical tower.

Several studies focused on the astronomical function of the tower because it has some ducts going through the solid core of the cylinder (Andrews IV, in Aveni, 2005, p. 383; Benavides, 1999), but the interpretations on the nature of this building remained incomplete. Because of this, some authors mentioned that the function of cylindrical tower must remain as a "mystery," at least for now (see Aveni, 1991, pp. 306–308, 2005, p. 383).

Recent researches have proceeded on the interpretation of this "enigmatic" Maya building and a preliminary interpretation can be found at Higón Calvet and May Castillo (2011), but it is not the last word on the nature of this beautiful and unique sample of Maya architecture (Fig. 1).

Puerto Rico Tower

Manuel May Castillo¹ and Felix A. May²

¹Archaeology Faculty, Leiden University, Leiden, The Netherlands

²INAH México, Mexico City, Mexico

Puerto Rico's cylindrical tower represents a unique case in Maya typologies of architecture.

Description

The tower is located in the municipality of Xpujil, Campeche, Mexico. The name of the site comes from the nearest community, called Puerto Rico. The tower is an architectural monument within an ancient Maya settlement (maybe a city-ceremonial center). The cylindrical tower is located at the center of a square (in Yucatec: *Chúumuk kaaj*), and other buildings can be found at the surroundings, but they remain still buried.

Puerto Rico Tower, Fig. 1 Puerto Rico's tower (Modified from Higón Calvet and May Castillo 2011)

No archaeological researches have been made in order to learn the nature of the other buildings; the only interest is in conservation of the tower. It is currently within an agricultural area (*milpas*) in the middle of the jungle. There are no guards at the site; nevertheless people from the community keep it safe.

Form

The morphology of this building can be divided, for purposes of analysis, into two parts: the main cylindrical body and the rectangular basement. The cylindrical body has 12 small ducts; some of them pierce its solid core. The cylinder has an elliptical section of 2.90 m at its main axis. The base is a rectangular prism, with curved corners and four elements added at each side; all of them resemble staircases. The base measures approximately 4.32 and 4.54 by side. The overall height of the tower is 7.45 m approximately, although originally it was higher. Benavides found the tower partially collapsed, and he only restored and consolidated the part still standing (Fig. 2).

Constructive System

The constructive system is in Rio Bec style. It consists of small ashlar [hewn or squared stones]

finely carved in the curved section, covering a solid core of masonry and calcium mortar. The tower is apparently a masterpiece of Rio Bec style. Previously, there were cylindrical columns of Hormiguero's structure II and the squared towers of Xpujil, Rio Bec, and Hormiguero sites, which are curved at the corners, similar to the base of Puerto Rico's tower. If we visit the sites of the Rio Bec region, we can find several beautiful samples of architecture which confirm the existence of master architects within a small area, who were using their creativity and experience in order to create unique masterpieces, such as the cylindrical tower at Puerto Rico.

Since carved ashlar were also found within the solid core (Benavides, 1999), we can confirm the ancient tradition of Maya builders: old buildings are reused to build a new one. In most cases, the old building is covered by the new one, as a first constructive layer. Of course, other cases only use parts of an ancient building, as in the Puerto Rico tower, at least in the cylindrical solid core.

The ducts are also made following Maya traditions; the ashlar are displaced some few centimeters in a certain row, but not in the next row, so we have a kind of small window made only by variation of separation between ashlar. At the interior of the solid core, two rows of ashlar are aligned and parallel to the axis of the duct. Horizontal slabs are placed at the top of the ashlar, shaping the ducts and also contributing to the mortar which fills out the core. Horizontal slabs are found not only in the Maya region but also in Mesoamerica, where we can find some tombs covered with horizontal slabs. As an example, we can mention the Monte Alban tombs.

Understanding

In the recent past, some scholars stated that one of the functions of the tower had to do with astronomical observations (Andrews IV in Aveni, 2005, p. 383; Benavides Castillo, 1999; Higón Calvet & May Castillo, 2011). But before continuing with this argument, we have to refine the statement of the astronomical function. First of

Puerto Rico Tower, Fig. 2 Map of Puerto Rico's cylindrical tower (Modified from Higón Calvet and May Castillo 2011)

all, we are not dealing with an astronomical observatory as it is understood in Western cultures. We are dealing with a building which integrated astronomical knowledge in order to transmit a set of deep messages related to the Mesoamerican cultural context. The minimalist concept of architectural design is the opposite of its symbolic complexity, as we will see below.

Continuing with the astronomical argument, the ducts were the evidence on which previous studies based their hypotheses of the tower's astronomical function. Since 1969 some authors argued that these were part of an astronomical system of observation. Nevertheless Aveni (1991, pp. 306–308, 2005, p. 383), after his field-work, argued that there were no reasons to consider the ducts as astronomical apparatus. Later

Benavides (1999), after his restoration, reported new ducts in a second level (which apparently were not detected by Andrews IV, Aveni, and others) and argued that there were some ducts pointing to positions of the Moon, the Sun, and other celestial bodies on the horizon line. Higón Calvet and May Castillo (2011), after revisiting the site, made new analyses considering their own data and Benavides' data. The authors confirmed some statements of Benavides, and they added that one of the ducts (C-F) points to a certain position of the Sun on the horizon, which marks the sunrise on the days when it passes through the zenith.

But, the tower is more than a building for astronomical ducts. Excavations of Benavides showed that the base of the building was not

conical as previous researchers thought. The base is squared and includes four altars like small staircases at each side. The base is oriented to the Four Directions of the Maya World. This means that deep symbolism is embedded in the architectural plan of the tower.

The Maya and Mesoamerican World have four main directions, related to four colors, and several deities are located at those four regions of the World. The regions of the World and their deities can be seen on pages 75–76 of the Maya codex at Madrid and also at page 1 of codex Fejérváry-Mayer from Central Mexico. The Maya (and Mesoamerican) World also has four corners which have sacred trees and birds. In the center of the diagram of codex at Madrid, we can see a central element which resembles a tree or central axis. The central axis of the World is a recurrent topic in several cultures around the world (see Eliade, 1974, pp. 269–271), and within the Maya worldview, the *Ya'ax che'* (ceiba tree) is, in a certain way, related to the *axis mundi*.

So, the base and altars can be related to the Four Directions and their deities. The cylindrical element appears as a central axis in this composition. At this point, we have to review the interpretations of the ducts.

Andrews IV suggested that the ducts were a sort of “psychoducts” similar to those found on the funerary monuments at Andean culture. “Psychoducts” would be open channels to communicate with the spirits of the people buried underneath the tower. But, Aveni argued that there is not enough archaeological evidence to consider the tower as a funerary monument. Actually, there were no excavations in the solid core of the base, but archaeological evidence points to ritual activities at the tower (Benavides Castillo, 1999). Additionally, the directions of the ducts seem to point to the Four Directions of the World and its corners, where deities are located. I agree with Aveni that there is no evidence for relating the tower with a funerary monument, but the idea of communicating with spiritual levels of the World (suggested slightly by Andrews IV) seems to be appropriate. If we are with contemporary Maya peoples, we can see

that ancient traditions are still alive, and the deities of the Four Directions are called to take part at contemporary rituals. So, the ducts could materialize the communication channels towards the spiritual level (a wider interpretation on the ducts can be seen at May Castillo 2014, pp. 379–382).

Since Higón Calvet and May Castillo state that the duct C-F points to zenith passages, we cannot reject the astronomical function of the cylindrical tower, but must always keep in mind the cultural context where the observations of the Sun are carried out. In other words, if the zenith passages were observed by the duct C-F, the meaning of this astronomical event has to do with Maya dates on the ancient calendar. The date has significance in terms of agriculture, because it indicates the beginning of the rainy season (see also Broda, 2004), and the religious rituals performed at the tower could be related to agricultural activities. But other religious rituals could be performed as well; we have to remember that there are more ducts than C-F and they are pointing to deity's localities.

Other towers in Tabasqueño, Chenchán, and Nocuchic have been related to zenith passages in the Maya region (Tichy, 1992), but the mechanism proposed for registering this astronomical event is by projecting shadows of stone “ledges.” Franz Tichy's hypothesis is very interesting, but it is based only on astronomical phenomena, and he does not link his argument with the ancient and contemporary Maya worldview. Those towers are squared in their horizontal section, so there are no similarities between them and Puerto Rico's cylindrical tower. Puerto Rico's tower remains a unique case where it is apparently pointed to the sunsets when the Sun passes through the zenith.

On the other hand, Benavides and Higón Calvet and May Castillo argued that other ducts are related to equinoxes and solstices, but there are enough reasons to believe that equinoxes and solstices were concepts of a Western worldview imported during colonial times (see May Castillo, 2014, pp. 167–171). Of course, there are some architectural orientations to the extreme positions of the Sun, but I believe they are pointing towards the corners of the Maya World. The ducts E and

F of the first level are pointing towards the center of the east and west directions, where two deities are located at each center.

State of Preservation

The fieldwork at Puerto Rico's tower in 2010, carried out with Félix May (a guard from the Instituto Nacional de Antropología e Historia and an expert on Maya culture), allows us to register the state of preservation of the tower, having in mind that it was consolidated and restored in 1999. Almost 11 years after Benavides intervention, the tower has been affected by natural agents; rainy and dry seasons stress the surface of the building, and this probably has destroyed some stucco remains which Benavides found. In 2010 there was a tree rotting at the top of the tower. Because of this, some cracks have appeared at the surface, and they were heading towards the solid core. Additionally, the forest surrounding the tower is often burnt during the dry season, when the temperature is about 40 °C.

Final Words

Puerto Rico's cylindrical tower is a unique masterpiece of Maya architecture. It has embedded both the fundamental symbolism of the Maya worldview and also some astronomical knowledge. Nevertheless its nature is still not completely understood. Future researches on the tower will shed more light on the understanding of Maya culture and its technologies.

Unfortunately the cylindrical tower remains endangered. It is attacked every day by natural phenomena and also by pathologies which must be stopped as soon as possible. If this does not occur in the near future, the building will collapse (at least partially) as has occurred with one of the Nocuchic's towers, which completely collapsed. And of course we, the scholars, will miss a unique opportunity to do research on an exceptional sample of Maya architecture.

Putumana Somayāji

K. V. Sarma
Madras, Tamilnadu, India

Putumana Somayāji (ca. 1660–1740), author of the work *Karaṇapaddhati* (Methodology for Astronomical Manuals), was a *nampūtiri* (the appellation of the Brahmin community of Kerala in South India) who belonged to a family which bore the name Putu-mana (New House). He was of ṛgvedic denomination and secured the surname Soma-yāji by having performed the Vedic *Soma* sacrifice. His real name remains unknown.

K. V. Sarma: deceased.

The date of Soma-yāji is surmised on the basis of the chronogram which gives the date of completion of his *Karaṇapaddhati* (as 17,65,653) of the Kali era, stated in the *kaṭapayādi* notation of expressing numerals, which is in the year AD 1732. Again, in the concluding verse, Somayāji states that he hailed from the village named Śivapura, which has been identified as Covvaram in Central Kerala, where his descendants still reside.

Somayāji was a prolific writer mainly on astronomy and astrology, his only work in a different discipline being *Bahvṛcaprāyaścitta*, a treatise which prescribes expiations (*prayāścitta*) for lapses in the performance of rites and rituals by Bahvṛca (ṛgvedic) Brahmins of Kerala. In addition to his major work, Somayāji is the author of several other works. In *Pañca-bodha* (Treatise on the Five), he briefly sets out computations at the times of *Vyatipāta* (an unsavory occasion), *Grahaṇa* (eclipse), *Chāyā* (measurements based on the gnomonic shadow), *Śṛṅgonnati* (elongation of the moon's horns), and *Mauḍhya* (retrograde motion of the planets), all of which are required for religious observances. His *Nyāyaratna* (Gems of Rationale), available in two slightly different versions, depicts the rationale of eight astronomical entities: true planet, declination, gnomonic shadow, reverse shadow, eclipse, elongation of the moon's horns, retrograde motion of the planets, and *Vyatipāta*. Three short tracts on the computation of eclipses, including a *Grahaṇāṣṭaka* (Octad on Eclipses), are ascribed to Somayāji. He also composed a work called *Veṇvārohāṣṭaka* (Octad on the Ascent on the Bamboo), which prescribes methods for the computation of the accurate longitudes of the moon at very short intervals. A commentary in the Malayalam language on the *Laghumānasa* of Muñjāla is also ascribed to him. On horoscopy, Somayāji wrote a *Jātakādeśa-mārga* (Methods of Making Predictions on the Basis of Birth Charts), which is very popular in Kerala.

The *Karaṇa-paddhati*, in ten chapters, is his most important work. The work is not a manual prescribing computations; rather, it enunciates the rationale behind such manuals. Toward the

beginning of the work, the author states that he composed the book to teach how the several multipliers, divisors, and R sines pertaining to the different computations and the like are to be derived. Thus, the work is addressed not to the almanac maker but to the manual maker. All the topics necessary to make the daily almanac are not treated in *Karaṇapaddhati*, whereas several other items not pertaining to manuals are dealt with. The work takes as its basis the parameters and postulates of the Parahita system of astronomy promulgated by Haridatta, except for the section on eclipses, where the more accurate system from the *Dr̥ggaṇita* of Parameśvara is taken as the basis.

In Chapter I, the *Karaṇapaddhati* sets out the planetary parameters, the computation of the mean planets, and the corrections to be applied thereto. Chapter II is devoted to the derivation, by means of pulverization (*kuṭṭaka*), of the multipliers and divisors necessary for planetary computations. Chapter III is concerned with various aspects of the computation of the moon, and Chapter IV deals with miscellaneous matters relating to the determination of suitable epochs for commencing computations. Chapter V mentions methods for correlating observed results with computed results, while Chapter VI depicts such matters as the circle and the circumference and the R sines pertaining to various entities for different purposes. Chapter VII is devoted to the rationale of the derivation of the mnemonics relating to the epicycles, their R sines, and allied matters. Chapter VIII describes varied derivations using the gnomonic shadow. Chapter IX is devoted to stellar declination and latitudes. The last chapter is concerned with certain derivations from the shadow of the gnomon.

As a work on astronomical rationale and exposition of the logic of several practices, the *Karaṇapaddhati* is highly important. A very significant statement made by the Putumana Somayāji, toward the close of Chapter V, is that the conception of eons and eras, the measures therefore, and the various derivations based on them are not really true; they are only a means to compute the positions of celestial bodies and matters related to them. What is really important

is the correlation of computation with observation, and to effect the same, a practical astronomer is authorized to make changes as necessary. This is a highly significant statement, maybe even revolutionary, which was made in a forthright manner by an orthodox Hindu astronomer.

Pyramids in Egypt

Gregg De Young

The American University in Cairo, Cairo, Egypt

The pyramids of ancient Egypt still stand overlooking the Nile, bearing mute testimony to the civilization that constructed them nearly 5,000 years ago. Considering the magnitude of the effort expended, it seems surprising that no information about their planning or construction has been preserved. Such mysteries have generated an incredible array of hypotheses and suppositions concerning both construction techniques and cultural implications of the pyramid.

History

The origins of pyramid construction are obscure. The Step Pyramid of Third Dynasty Pharaoh Djoser (ca. 2667–2648 BCE) at Saqqara appears to be an elaboration of earlier funerary architecture, combining First Dynasty *mastaba* forms (low, flat mud brick, or stone superstructure above a subterranean burial vault and storage compartments) with the large, mud-brick-walled funerary enclosures of the Second Dynasty. Djoser's pyramid appears to be a first experiment in large-scale stone construction. Beginning as a mastaba, it was enlarged horizontally several times before building upwards, perhaps because the original low mastaba was not visible behind the wall surrounding the complex. A passage on the north led to a subterranean burial chamber with 11 subsidiary burial chambers. The adjoining storage chambers and corridors were decorated with blue faience tiles and relief sculptures of Djoser.

The Step Pyramid is only the most obvious structure on the site. Also inside the enclosure wall are temples, pavilions, mastaba-like tombs, chapels, as well as extensive storage structures. Most important of these was the mortuary temple placed on the northern side of the pyramid in imitation of the offering chapels attached to archaic mastabas, where offerings on behalf of the dead Pharaoh might be made. Early mortuary orientation to the north is taken to indicate a focus on the undying circumpolar stars in the northern sky. (In later pyramid complexes, the mortuary temple would be placed on the eastern side, facing the rising or reborn sun.)

The experiment in stone construction must have been regarded as a success, for the pyramid was rapidly developed in the Fourth Dynasty. The Pharaoh Sneferu (ca. 2613–2589 BCE) erected two pyramids at Dahshur, south of Saqqara. The Bent Pyramid's distinctive outline, with its shift from 54° to 43°, showed the necessity for a solid foundation. Built with much larger stones than the Step Pyramid of Saqqara and placed directly on the desert surface, subsidence, combined with less stable inward-sloping core blocks, soon introduced internal stresses that

caused fissures to appear in the structure. Apparently hoping to relieve some of the internal stresses, the builders changed the slope of the pyramid, but the damage to the structure was beyond repair. Learning from experience, Sneferu's architects then constructed the Red Pyramid a kilometer to the north of the Bent Pyramid. Here, although they retained the relatively shallow 43° angle, the builders first laid a solid stone foundation and then built on it with horizontal courses of stone to produce the first completely successful true pyramid. These early Fourth Dynasty pyramid complexes reveal the basic features characteristic of later pyramids. The pyramid is typically the focal point of an east–west oriented rectangular enclosure, containing an offering temple on the east side of the pyramid and often one or more subsidiary pyramids. A causeway, usually covered, led from the pyramid complex down to a valley temple near the banks of the Nile.

Following on these early experiments, the great pyramids of Giza were constructed. The largest was created by Sneferu's successor, Khufu (ca. 2589–2566 BCE). Two somewhat smaller pyramids belong to his son, Khafre (ca. 2558–2532 BCE) and grandson Menkaure (ca. 2532–2503 BCE). These pyramids mark a high point in terms of sheer physical size and engineering prowess. The Fifth Dynasty pyramids at Abu Sir are often held to represent the highest development architecturally of the pyramid complex and associated valley temple, although the pyramids themselves are distinctly smaller in size. They also reveal a significant decline in workmanship, perhaps paralleling the decline of centralized authority in the state. Their interior blocks were scarcely shaped, and the removal of the limestone casing blocks has left most of them looking like little more than piles of rubble.

Royal burials between the Sixth and Twelfth Dynasties largely abandoned the pyramid form. When it was revived in the Twelfth Dynasty (ca. 1895–1795 BCE), both construction material and construction techniques had changed considerably. The interior structure often consisted of little more than stone cross walls to give solidity

and rigidity to a mud brick or rubble-filled structure. The pyramids continued to be faced with high-grade limestone, however, and so would externally have looked very similar to earlier pyramids. They would have been more economical to build, however, since they require a considerably smaller workforce, as well as utilizing cheaper building materials.

By the end of the Thirteenth Dynasty, pyramids had once again been abandoned for royal burials. In the Nineteenth and Twentieth Dynasties (New Kingdom), however, small pyramidal structures often surmounted the funerary chapels of nonroyal burials. Important examples appear in the cemetery associated with Deir el-Medina, the town housing the workers who constructed the rock-cut tombs in the Valley of the Kings and Valley of the Queens, the new royal necropolis on the west bank of the Nile opposite Thebes.

Nearly 1,000 years passed before the pyramidal form was reclaimed for royal burials by the Nubian kings. Their pyramids are constructed from blocks of local sandstone. They have steep sides (approximately 70°) and are relatively small. Their apex is often flat. The burial chamber was not constructed inside or underneath the pyramid. Rather, the burial chamber, often decorated in Egyptian style motifs, was constructed, and then the pyramid was erected above it. The pyramid fields at Nuri and el-Kurru (above the fourth cataract) were constructed mainly between 770 and 400 BCE. Meroe (between the fifth and sixth cataracts) was an active necropolis until nearly 350 AD. These sites contain more pyramids than have been discovered in the Nile Valley.

Construction Techniques

The pyramid of Khufu involved quarrying nearly 2.5 million blocks of limestone weighing on average between 2 and 3 t, transporting them to the building site, and raising them into place. If the report of Herodotus, that the pyramid was completed in 20 years, is to be believed, this would require moving a block into place approximately every 3 min – a remarkable achievement indeed.

Although no documentary evidence has ever been found, there is ample circumstantial evidence to suggest that Khufu's pyramid was carefully planned, taking into account what had been learned in earlier construction attempts. The builders constructed a level foundation directly on the bedrock. The early suggestion that the site was leveled by surrounding the entire site with a low mud wall, filling the enclosure with water, and digging a series of trenches at uniform depth below the surface of the water (the intervening material could easily be removed later) no longer appears credible, but the precise technique remains rather mysterious. Most probably it was done by adjusting the foundation stones to provide a flat plane on which to build, a process that might be accomplished by using a simple A-frame tool to assess the leveling of the surfaces.

These pyramids are also remarkable for their accurate alignment with the four cardinal directions. This alignment must have involved some sort of astronomical technique. One suggested procedure involved bisecting the angle between the rising and setting point of a star in order to determine true North. Although this method sounds simple, it would require the construction of an artificial level horizon and very precise observations in order to obtain the observed accuracy of alignment. A somewhat easier technique would require erecting a gnomon perpendicular to the surface of the earth and constructing a circle about it with some convenient radius. It is then necessary to mark the two points during the day when the tip of the gnomon's shadow touches this circle, connect these two points to the gnomon, and bisect the angle so produced in order to determine true North. Although requiring simpler equipment, the observations must still be made with careful accuracy in order to produce the orientation we observe in Khufu's pyramid.

Large quantities of stone had to be quarried and transported to the building site. Extracting blocks of relatively soft local limestone for use in the core of the structure posed no technical difficulty for the ancient Egyptians. The stone block could be defined using traditional flint axes and

separated from the rock matrix with wedges. The quarries for the bulk of the stone lie on the Giza plateau almost below the pyramid building site itself. Facing blocks of high-grade limestone were brought from Tura, on the other side of the Nile. Granite, used in facing the corridors and chambers within the structure, had to be quarried in Aswan and transported to Giza by boat or barge. A very hard Plutonic stone, it required the use of dolerite mauls to work, since copper and even bronze were too soft to be effective. Recent experiments have shown that heating the stone using fire and then rapidly cooling the area with water causes the granite to fracture much more easily.

Once separated from the bedrock, the limestone core blocks were transported to the building site on wooden sledges pulled by teams of 15–20 men – more if massive blocks needed to be moved. The sledges could travel across firm surfaces using sets of wooden rollers as a kind of primitive wheel. If it were necessary to transport the blocks over sand, friction might be reduced by constructing a primitive roadway, embedding timbers in the desert surface on the pattern of railway ties or sleepers. When wet, the wooden sledge would slide quite easily across these wooden beams. There is still no conclusive evidence to indicate whether dressage occurred at the quarry sites or at the construction site.

Once at the pyramid site, the blocks had to be raised into position. The most prevalent view is that this involved recourse to a system of ramps, although there is no agreement on straight or helicoidal ramps spiraling around the exterior of the pyramid. Either proposal requires considerable construction of an ancillary structure that would later need to be removed. Opponents of ramps question where the evidence for removal of such large-scale ramps is. (Perhaps it was simply dumped into the quarries.) The most common alternative suggestion has been the use of some form of jacking mechanism, either directly through levering or indirectly through the use of "cradles" equipped with rockers that could be pushed to one side or the other while wooden planks were placed under the elevated side to raise the structure. (Examples of such rocker

cradles have been found near construction sites.) In practice, however, raising blocks to the level of about a meter using jacking techniques is difficult because the supporting structure rapidly becomes less stable with increased height.

More recently, a suggestion has been made that the “cradles” were not intended for rocking the stone upward, but that four cradles, attached to the faces of the block, might function as a kind of primitive wheel. A few preliminary tests indicate that such a configuration might work to move stones up a ramp. Another recent suggestion does away with both jacking and ramps, arguing that the blocks were simply pulled up the side of the pyramid mounted on their sledges and lubricated with water. This hypothesis would explain why there is little evidence of ramps surviving at the work site. It would also presuppose that the finished casing blocks must have been put in place immediately on completion of each course of core blocks. It also leaves open questions about the upper courses, where men would have had less room for maneuvering while raising the blocks a longer distance. Each theory has some merit to recommend it, as well as practical difficulties in application. It is likely that there was no single method used in every pyramid; probably an array of techniques was employed to solve these technical problems in various contexts.

In addition to the physical problem of raising sizable limestone blocks to a considerable height, it was necessary to control the shape of the pyramid in order to avoid deformations. Once again, we do not know exactly how the ancient Egyptians solved such problems. One simple-sounding technique would be to measure the sides at each course of stone to make sure they are still square (assuming that one had successfully laid out a square base), or perhaps each course was checked by sighting across the pyramid on the diagonals. But actually carrying out such operations might prove difficult. Measurement would require either the repeated application of a rigid measuring rod, which could allow small errors to cumulate over long distances, or use of a measuring rope, which would be subject to stretching or sagging and so also allows for

incursions of significant error. In this case, too, it is possible that various techniques were tried in various combinations on each pyramid that was constructed.

From very early dynastic times, there was a clear concern for security of tombs (including burial chambers within or below pyramids). Considerable treasure was interred with royalty, and wealth inevitably attracts robbers. Already at the construction of the Fourth Dynasty Bent Pyramid, we find the use of a portcullis system by which large (usually granite) blocks could be lowered to block passages leading to the burial chamber. Sometimes these portcullis blocks came with a kind of locking device to prevent robbers from lifting them with levers: a short rod would be placed in a small shaft at the side of a portcullis channel just above the height of the portcullis block and angled so that when the portcullis was lowered, the wooden rod would protrude into the channel, thus blocking any attempt to raise the portcullis using levers. In practice, such devices rarely delayed robbers long. They simply tunneled around or over the portcullis. Equally ineffective were the efforts to provide a means to block entrance tunnels with great blocks of granite drawn into the passage from the side or the use of gravity to slide granite blocks into a passageway, blocking access to the door to the burial chamber. Again, robbers were likely simply to tunnel past these obstacles. The lure of riches left no pharaoh undisturbed for long.

Pyramid Workforce

Herodotus, the Greek traveler who visited Egypt about 450 BCE, was told by his informants that it had required 100,000 slaves laboring for 20–30 years to build the pyramids of the Giza Plateau. Modern scholarship has painted a quite different picture. Mark Lehner has excavated a large urban complex on the Giza Plateau, separated from the pyramid worksite by a massive stone wall. This urban complex contained what appear to be barracks for workers, bakeries, and fish-processing installations big enough to produce

food for several thousand workers. It is believed that a contingent of about 5,000 skilled stoneworkers, together with a contingent of support personnel, were in residence in this center all year round. During the inundation period, there would be an influx of several thousand unskilled workers to provide the basic manual labor of cutting and moving stones from the quarries and from the harbor. These estimates coincide reasonably well with those made by a modern engineering firm who attempted to estimate the workforce based on application of techniques used to plan modern large-scale construction projects.

Zahi Hawass excavated the tombs of workers associated with the pyramid building process. These tombs imply that the builders were not slaves, for no slave would be able to construct a tomb out of rock nor would slaves have the financial means to decorate their tombs with inscribed and painted hieroglyphs. Analysis of the skeletal remains from the tombs shows distinct signs of heavy toil but also shows a level of medical care that would have been highly unusual for a slave population. Further, DNA analysis shows that these workers were certainly Egyptian, not enslaved foreigners or military prisoners.

This workforce was highly organized. A “crew” of about 2,000 was subdivided into two gangs, each of about 1,000 men. Each gang was further subdivided into five phylae (*zaa*), each containing 200 men. Each phyle was subdivided into 10 groups of 20 men each. Evidence for such a division of workers comes from graffiti left behind by members of the various groups. This hierarchical organizational plan was copied whenever large groups of people needed to be organized efficiently – for example, in the staff of the large cult temples.

Pyramids of Mesoamerica

Geoffrey Mccafferty

The construction of monumental architecture is one of the archaeological hallmarks of social complexity. It involves the ability to mobilize and coordinate labor; it requires surplus manpower and material; it implies sophisticated knowledge of architecture and engineering; and it assumes a fair degree of administrative control. In evolutionary terms, monumental architecture appears when there is a fairly high degree of complexity, with multitiered political organization in what can be characterized as “chiefly” or “stratified” society. In pre-Columbian Mesoamerica, this level of complexity first appeared in the Early Formative period, ca. 1200 BCE, among the Olmecs of the southern Gulf Coast. In time other cultures also adopted monumental architecture for primarily religious purposes but also as a legitimization of political authority.

The most typical form of monumental architecture used in Mesoamerica was the pyramid. Pyramids were often perceived as artificial mountains, and they represented attempts by the ruling elites to construct a symbolic landscape. Most pyramids were built to correspond to cosmological principles, such as astronomical orientation. They also represented the recreation of an axis

mundi, a world axis where the pyramid became the cosmic center around which the rest of the universe revolved both vertically and horizontally. Mesoamerican pyramids were literally a “stairway to heaven” where a select few could rise above the mortal plane to communicate with deities of the multitiered heavens in temples on top of the pyramid platforms. Similarly, many pyramids were constructed over natural springs, caves, or artificially created portals into the underworld for access to the deities residing there. A pyramid, therefore, was a conduit linking the three planes of the cosmos, where powerful ruler/priests could communicate with the gods and petition them for supernatural assistance. In part because of this symbolic centrality, Mesoamerican pyramids were often rebuilt by encasing the old structure within new layers of fill and façade to enhance the cosmic significance with a connection to the ancestral past, and thereby adding a temporal dimension as well.

Pyramids were fairly basic in their architectural form, with simple mounds of packed earth as the most simple style. Others were made of mounded earth and rubble, sometimes segregated in cells for internal integrity. The most elaborately built pyramid was the Great Pyramid of Cholula, where the internal structure is made up of stacked adobe bricks to create a remarkably stable interior. Note that with very few exceptions the interior of pyramids was solid, lacking inner chambers. The importance of a Mesoamerican pyramid was as a platform for one or more temples located on top.

Despite the relatively simple internal construction, however, Mesoamerican pyramids were often elaborately decorated on the exterior. The staircase was a natural focus of the building program, since it was the means of ascending to the temple. Staircases were often quite steep, making a direct vertical climb difficult, particularly for heavily robed priests. One speculation is that ascent was made in a serpentine fashion, moving up diagonally. Priests in colorful robes and elaborate feathered headdresses, climbing in procession, would appear to spectators below as a polychrome feathered serpent undulating up to the inner sanctum of the temple. As will be

discussed below, the Feathered Serpent god was a unifying theme of Mesoamerican religion, particularly as it relates to political legitimation and priestly knowledge.

Pyramid façades were generally finished in cut stone and covered with layers of stucco. Particularly in the Maya area they were often elaborated with symbolically significant carvings, often depicting powerful deities. The temples themselves were occasionally decorated with the image of the earth monster whose open mouth formed the temple entrance, a portal into the underworld. Maya temples also featured elaborate roof combs of stone rising high above the temple itself, created in lattice format to depict further cosmological images visible from great distances (Fig. 1). The Maya temples were constructed using the corbeled vault technique so that the weight of the roof and roof comb was transferred to the thick walls, in what was the crowning achievement of Maya structural engineering.

Mesoamerica, consisting of central and southern Mexico, Guatemala, Belize, Honduras, and parts of El Salvador, Nicaragua, and Costa Rica, is a culturally complex region that, during the pre-Columbian era, was often characterized by overarching similarities. Religious beliefs were one of these, and the use of pyramids was common to Mesoamerican cultures for over 2,500 years. Other commonalities included the calendar system, ritual ballgame, maize/beans/squash as dietary staples, and human sacrifice to appease the gods. Nevertheless, due to the cultural diversity some regional and temporal variations arose. The following is a brief survey of some of the important pyramids of Mesoamerica within their cultural contexts.

The earliest clear pyramid is known from La Venta and corresponds to the Olmec culture of the Middle Formative period (900–500 BCE). The pyramid itself is just one manifestation of a massive landscape modification as the ruling elite transformed the ceremonial center into a cosmogram that constructed their capital as the center of the universe. The pyramid itself is made of packed earth, and has been compared to an effigy volcano. The Olmec heartland is in the

Pyramids of Mesoamerica, Fig. 1 Example of a Maya temple with roof comb (Palenque)

swampy lowlands of the Gulf Coast, so this pyramid may be a reference to the volcanic Tuxtla Mountains to the north, from which much of their building stone was imported. A more revealing monumental construction was intentionally buried beneath the plaza in front of the pyramid, where thousands of imported jadeite bricks were formed into a mosaic image of the jaguar-like earth monster and then covered by layers of imported, colored clays to symbolize the layers of the underworld. Taken as a meaningfully constructed building program, the La Venta ceremonial center represents the symbolic relationship between the three levels of the cosmos, as well as a major investment in labor and resources.

In the Maya lowlands, sites such as Uaxactun, Nacbe, and El Mirador demonstrate monumental architecture during the Late Formative period. El Mirador features the El Tigre pyramid complex, one of the earliest Maya pyramids that was also the largest in terms of volume at 380,000 m³. Another early Maya pyramid is found at Cerros, where elaborate building façades are interpreted as representations of astronomical passages as the

sun traveled from east to west on its daily journey. A symbolic reading of this again suggests that the universe revolved around the Cerros pyramid. This probably relates to both religious beliefs as well as political propaganda, as jadeite jewelry cached at the site has been interpreted as an indication of the creation of a Maya *ahaw*, or king, suggesting a new level in political complexity.

Monte Albán, located in the southern highland valley of Oaxaca, represents another example of monumental architecture that was begun in the Late Formative period (500 BCE–200 CE), though modifications continued through the Classic period (200 CE–800 CE). Located on a ridge high above the valley floor, Monte Albán's acropolis was created first by flattening the ridge top to form a level surface, then by building numerous large buildings around a rectangular plaza (Fig. 2). The largest pyramid is the South Platform, that in its final manifestation consisted of a massive platform with a smaller pyramid located on top. While religious practices were probably paramount on this structure, numerous carved stone slabs depict political scenes

Pyramids of Mesoamerica, Fig. 2 Acropolis of Monte Albán

including captives and an emissary from Teotihuacan, emphasizing the interwoven nature of Mesoamerican religion and politics. The North Platform is even more massive, but probably had a more secular function. A wide staircase leads to a plaza where public rituals were likely held, before smaller passageways lead to a more restricted area that may have been the royal residence. Other smaller pyramids delimit Monte Albán's plaza, which is clearly outlined on the horizon and visible from the valley floor as a sort of "Big Brother is watching" political message.

In central Mexico the great urban center of Teotihuacan arose in the Late Formative period, and around 100 CE embarked on a major urban renewal program that included a rigorous grid system based on its Avenue of the Dead. The Avenue is oriented at 16° east of North, with a pecked cross marker in the bedrock of Cerro Gordo mountain as a datum point for aligning the Avenue. At the northern end of the Avenue is the Pyramid of the Moon, framed by Cerro Gordo behind it and actually designed to mimic

the form of the mountain (Fig. 3). To the south is the Pyramid of the Sun, the largest of Teotihuacan's pyramids, and it too mimics the shape of Otumba mountain in the distance. A third pyramid in the western part of the city is similarly set in relation to the natural landscape, perhaps as an intentional cosmogram in which the hills and the pyramids represent the three hearth stones symbolic of symbolic centrality.

Excavations beneath the Pyramid of the Sun discovered a long passageway, excavated into the volcanic bedrock for building materials but then modified into an artificial cave where rituals were performed. The form of the inner chamber resembles the flower shape of Chicomoztoc, the cave of origin from later Aztec mythology, suggesting that later peoples may have continued to worship in the artificial cavern at Teotihuacan. The entrance to this tunnel is beneath the west facing staircase onto the Avenue of the Dead, and therefore faces 16° north of west, the orientation of the setting Pleiades constellation which marks the beginning of the rainy season. It is possible,

Pyramids of Mesoamerica, Fig. 3 Teotihuacan's pyramid of the moon

therefore, that the entire urban renewal program around the Avenue of the Dead makes Teotihuacan an elaborate celestial almanac relating to the all-important rains.

Recent investigations into Teotihuacan's Pyramid of the Moon, as well as the Pyramid of the Feathered Serpent, have discovered sacrificial burials of warriors, perhaps as dedicatory offerings to the lords of the underworld. These burials are clustered in groups of 9, 13, and 20, numbers symbolic of cosmological principles including the sacred 260-day calendar. The stone façade of the Feathered Serpent Pyramid features a long rattlesnake body (covered in feathers) undulating in profile but with a front-view head surrounded by more feathers (Fig. 4). This image is generally identified as a "feathered serpent" but is also similar to the *axolotl*, a species of salamander that lives in the lakes of central Mexico and has feathery gills that encircle the head. On the back of the serpent is an elaborate mosaic headdress representing political office (a similar scene adorns the mosaic façade of the Nunnery Compound at the Maya site of Uxmal). Curiously, the west façade of the Pyramid of the Feathered Serpent was covered over by later construction to obscure, and thereby unintentionally preserve, this iconographic program.

Pyramids dot the Classic Maya landscape where, because of the prevalence of textual

evidence on carved stone markers, they can occasionally be related to the particular ruler who commissioned their construction. Some of the most impressive pyramids come from Tikal, the capital of a Maya "superpower" of the sixth through ninth centuries. For example, Temple I reached 52 m in height, with its temple structure and roof comb reaching above the current jungle canopy (Fig. 5). Contemporaneous with these is the Temple of the Inscriptions from Palenque, where extensive hieroglyphic texts record the lineage history of King Pakal. A trapdoor in the floor of the temple led to a passageway down through the pyramid itself to a subterranean chamber where Pakal's sarcophagus was found (Fig. 6). This use of a pyramid to enshrine a ruler is unusual in Mesoamerica. Other pyramids at Palenque include the Cross Group, where three small temples represent the three hearth stones, a Mesoamerican metaphor for the cosmic center. Another major Maya center was Copán, located in modern Honduras. It is famous for its elaborately decorated architecture and the many carved stone stelae that recount dynastic histories. Its largest pyramid was Temple 26, known for its hieroglyphic staircase representing the longest known text in the Mayan language; unfortunately early explorers stripped the carved stairs from their original position before randomly replacing them out of order so attempts at decipherment are still furtive.

Pyramids of Mesoamerica, Fig. 6 Palenque's temple of the inscriptions, indicating passage to a subterranean crypt

Following the collapse of Teotihuacan and Monte Albán at the end of the central Mexican Classic period (ca. 700–800 CE), Maya influences in the central highlands of Mexico resulted in architectural innovations that affected pyramids at sites such as Xochicalco, Cacaxtla-Xochitecatl, and Cholula. Similar to Monte Albán for the scale of modifications to the natural hilltop, Xochicalco is best known for its Temple of the Feathered Serpent. Large feathered snakes curl around the walls of the pyramid base, with Maya-style lords seated within the curves of the serpent's body (Fig. 7). Glyphic inscriptions in a non-Maya – and as yet undeciphered – script likely describe conquests and/or political alliances. Cacaxtla boasts beautiful polychrome murals, again in Maya style, on the walls of Building B at the north end of its acropolis. The murals depict the aftermath of ethnic conflict between an army with Maya costume and physiological traits, who have been defeated by another group. As a result of this battle the female war-chief of the Maya group is captured, perhaps to become the founding queen of a new, united lineage. On the adjoining hill of Xochitecatl, the Pyramid of the Flowers was likely dedicated to a

goddess cult. The staircase is made up of basalt grinding stones, an artifact closely associated with female domestic practice. On top of the pyramid, caches contained dozens of female figurines depicting different phases of the female life cycle, especially motherhood, and also hundreds of clay spindle whorls, another characteristic of female practice.

The largest pyramid in Mesoamerica is at Cholula, located in the Puebla/TLaxcala valley east of Mexico City. It was built in successive stages over a period of over 1,000 years (Fig. 8), and it remains an important religious site with its Colonial church dedicated to the Virgin of the Remedies perched on top and attracting tens of thousands of pilgrims annually. The Great Pyramid of Cholula is known as *Tlachihualtepetl*, literally an artificial mountain. Its construction history has been studied using 8 km of tunnels cut through the adobe brick construction to reveal at least four major construction stages. The final stage measured at least 400 m on a side, and 65 m in height (although the construction of the Colonial church undoubtedly destroyed the uppermost levels). The Great Pyramid was oriented toward the setting sun at summer solstice,

Pyramids of Mesoamerica, Fig. 7 Temple of the feathered serpent at Xochicalco

Pyramids of Mesoamerica, Fig. 9 Puuc architecture at Chichen Itza

the longest day of the year, so that the temple on top of the pyramid would have been the last place illuminated by the setting sun.

The relationship between Maya and central Mexican architecture is particularly strong at the sites of Chichen Itza, in northern Yucatan, and Tula, located far to the west. Chichen Itza features Puuc style architecture with elaborate stone mosaic work to create geometric patterns and visages of deities (Fig. 9). But it also has other architecture with distinctive features that have traditionally been labeled “Mexican” following ethnohistorical accounts that Toltecs from central Mexico invaded the region. This interpretation has been challenged, however, with new dates that suggest that Chichen predates Tula, the highland capital of the Toltecs. Numerous decorative features from both Chichen Itza and Tula are virtually identical, including the use of reclining Chacmool thrones, feathered serpent columns, and colonnaded areas. The close similarities between the two sites has led many to suspect that the two were eastern and western capitals of an extensive Toltec empire, but a near total lack of related elements in the intervening territory adds to the enigmatic status of the two sites. The large pyramid at Chichen Itza is

notable because of the feathered serpents that flank the radial staircases (Fig. 10). The pyramid is oriented so that, at the spring equinox, shadows formed by descending serpents appear to undulate down to earth; this phenomenon is a popular tourist attraction drawing thousands to witness the illusion, including living Maya who continue to revere the site. At Tula, north of modern Mexico City, the ceremonial center has a nearly identical plan (albeit 90° off from Chichen Itza). Pyramid B closely resembles Chichen Itza’s Temple of the Warriors, with stone warriors as building columns that must have supported the roof (Fig. 11).

The Gulf Coast site of El Tajín does share some iconographic characteristics with Chichen Itza, especially in the use of elaborately carved columns and ball court. Narrative qualities of the carvings seem to relate to political legitimization and alliance building, again emphasizing the ideological content of the built environment. The major pyramid at El Tajín is known as the Pyramid of the Niches, named for 365 empty niches that decorate the façade (Fig. 12). Conceivably these would have originally held idols of gods associated with different days of the solar year. Large slabs at the base of the pyramid were

Pyramids of Mesoamerica, Fig. 10 The Castillo pyramid from Chichen Itza

Pyramids of Mesoamerica, Fig. 11 Pyramid B from Tula, showing warrior columns

drilled with holes where banners representing conquests or forged alliances would have been raised.

The final pyramid to be discussed is also the best known, though ironically it is almost

invisible today. When the Spanish entered the Aztec capital of Tenochtitlan in 1519, the Great Temple was the ceremonial center of the Aztec empire. Spanish conquistadors described the temple and associated rites of sacrifice, and artists in

Pyramids of Mesoamerica, Fig. 12 Pyramid of the niches at El Tajin

Pyramids of Mesoamerica, Fig. 13 Depiction of great temple in Codex Duran

the early Colonial period illustrated the Temple. Typical of Aztec pyramids, the Great Temple featured two temples atop a single pyramid base. These were dedicated to Huitzilopochtli, the patron god of war, and Tlaloc, god of storms and rain (Fig. 13). However, shortly after the

Spanish defeated the Aztecs they tore down the Great Temple to build their own Colonial capital. Fortunately for later archaeologists the lowermost levels of the pyramid were preserved beneath the rubble (Fig. 14). When utility workers dug at the site in the 1970s they chanced upon a

Pyramids of Mesoamerica, Fig. 14 Excavated great temple of Tenochtitlan

massive carved stone representing the dismembered moon goddess Coyolxauhqui, and based on this discovery a monumental excavation project was begun by the Mexican government to expose the remains of the Great Temple. According to Aztec myth, the Great Temple represented the serpent mountain, Coatepec, where Huitzilopochtli killed his sister, Coyolxauhqui, while defending his mother, Lady Serpent Skirt/Coatlicue. This mythico-historical drama was played out at the Great Temple, which featured serpent head iconography to make it “Serpent Mountain,” while the dismembered moon goddess lay at the base of the staircase. Archaeologists have found hundreds of ceremonial offerings at the Great Temple that further emphasize the symbolism of the site. For example, stone boxes contain layered dioramas of the three-tiered cosmos represented by successive layers of sea, land, and sky creatures. Sacrificial victims climbing the steps of the pyramid, only to have their hearts removed and their bodies hurled back down the bloody steps, were themselves participating in the mythic drama of creation and rebirth.

The Pyramids of Mesoamerica are among the most visible monuments of the ancient cultures of the region, and the stories that they tell are important clues to the belief systems of the people. Modern tourists marvel at the grandeur of these structures, built using Stone Age technology and without the benefit of draft animals or complex engineering. In fact, the pyramids of Mesoamerica are relatively simple mounds of rock and rubble, albeit decorated with often elaborate stucco façades. What is truly remarkable about these monuments is the meaning content that they embody, as cosmograms reenacting and centering cosmic forces, and as political narratives to legitimize the ruling elite. These pyramids encode important messages about Mesoamerican belief systems, and the critical yet imaginative interpretation of these monuments reveal the mythstories of the Mesoamerican world.

Q

Qāḍizāde Al-Rūmī

Gregg De Young

The American University in Cairo, Cairo, Egypt

Qāḍizāde al-Rūmī (Ṣalaḥ al-Dīn Mūsā b. Muḥammad b. al-Qāḍī Maḥmūd), one of the founders of Ottoman science and philosophy, was born in Bursa, in Turkey, about 765 AH/AD 1364. His talent for scholarship was early recognized, and his teacher, Mollā Fenārī, recommended that he continue his studies of mathematics and mathematical astronomy among the scholars of Transoxiana (a portion of Central Asia straddling the borders of present-day Uzbekistan and Kazakhstan), then a major center of scholarship and patronage. Consequently, about 814 AH/AD 1410, he migrated to the court of Ulugh Beg, governor of Samarqand (in what is now Uzbekistan) and serious amateur astronomer, and joined his retinue. He quickly gained favor with the court, in part because he dedicated his commentaries on al-Samarqandī's *Ashkāl al-ta'sīs* and on al-Jaghminī's *Mulakhkhaṣ fī'l-hay'ah* to Ulugh Beg.

In 824 AH/AD 1421, 4 years after establishing a major *madrasa* (school of advanced studies), Ulugh Beg decided to establish an observatory in Samarqand in order to complete and improve the data collected by Naṣīr al-Dīn al-Ṭūsī and his

assistants in the *Zīj al-Ilkhānī*. Al-Rūmī, along with his younger contemporary, Ghiyāth al-Dīn Jamshīd al-Kāshī (d. 832 AH/AD 1429), played an important role in both institutions. When al-Kāshī died, al-Rūmī succeeded him as director of the observatory. The work was still incomplete at the time of al-Rūmī's death (after 844 AH/AD 1440). It was finally completed by Alī Kushjī under the title *Zīj-i Jurjānī*.

Al-Rūmī also authored an influential commentary on Umar al-Jaghminī's (d. ca. 745 AH/AD 1345) compendium of cosmography, *Sharḥ mulakhkhaṣ fī'l-hay'a* (Summary Commentary on Hay'a/Mathematical Cosmography). In the field of mathematics, he is best known for his commentary on al-Samarqandī's *Ashkāl al-Ta'sīs* (*Fundamental Theorems*) [De Young, 2001]. These treatises had special appeal for al-Rūmī because they resonated with his Platonizing approach to mathematics [Fazlıoğlu, 2008]. His commentaries became standard texts to be read at the intermediate (*iktisar*) level in Ottoman madrasas. The influence of these two commentaries is also attested by the existence of numerous super-commentaries in Arabic, Persian, and Ottoman Turkish. Both commentaries were disseminated in lithograph editions during the nineteenth century.

Al-Rūmī's *Risālat al-jayb* (Treatise on the Sine) displays a greater independence of thought, but even here he relies on the iterative

techniques developed by al-Kāshī in order to find the sine of one degree.

Qanat

Arnold Pacey

The *qanat*, invented in Iran, is a tunnel that allows a well in hilly country to supply water to users on lower ground by gravity flow.

Once the well has been sunk and has proved to be a good source of water, the route of the tunnel is carefully surveyed, and a series of further wells or guide shafts is dug, each one about 300 m from the next. Excavation of the tunnel begins at the intended outlet and proceeds from the foot of one guide shaft to another. The depth of these shafts has previously been set, so that when the tunnel links them all together, it will have an even gradient of about 1:500. The head well may be anything from 15 to 100 m deep, and tunnels are frequently 2,000 m or more in length (Fig. 1).

As Andrew Watson points out, the history of the qanat can be clearly illustrated by a distribution map showing where water supplies of this kind are to be found. Before the time of Alexander the Great, i.e., before 330 BCE, about the only qanats known to have existed were in Iran. A thousand years later, around AD 700, qanats had been constructed in the Arabian Peninsula and Syria as well as in Persia. But then the Islamic people took up the qanat in a big way. Books were written on the subject in AD 840, and by al-ḥasan al-ḥāsib around AD 1000. Knowledge of the technique spread east to Afghanistan and west through North Africa to Morocco, Mauritania, and Spain.

Qanats continued to be developed in later centuries. By the sixteenth century, potteries were making earthenware rings for lining the tunnels where they passed through soft ground. In 1960, three-quarters of all water used in Iran came from qanats, with Tehran alone having 36 of them bringing water from hills several miles away.

The word “qanat” in Arabic is said to be the source of the English word “canal,” which was initially used to mean a pipe or tube or tunnel carrying liquid; it retains that usage in anatomy – hence, alimentary canal.

Qanat, Fig. 1 Two qanat tunnels in a typical landscape, where rainwater running off mountains replenishes groundwater beneath the sand and gravel of the lower slopes. (Water-bearing gravel is shown darker than the dry gravel layer above.) The ground penetrated by one of the qanats is shown in cut-away section to demonstrate how the tunnel gives access to water trapped by impervious rock. The section also shows how the tunnel is lined with earthenware rings when passing through sand or

gravel layers which might otherwise cave in. Qanat tunnels were excavated from the bottoms of a series of well shafts, with the “mother well” at the upstream end dug first to prove the existence of water. The tunnels were sometimes several kilometers long with their route evident on the surface from the line of well shafts, as on the right of the picture (Illustration by Hazel Cotterell based on sketches by Arnold Pacey. Reproduced from Pacey, 1990, p. 86)

Qasba in the Maghrib

Martin Malcolm Elbl

Maproom44 Ltd, Peterborough, ON, Canada

Qasba-s as fortifications fall into the broad category of power, status, and security artifacts. *Qasba* (*qaṣaba*, pl. *qaṣabāt* (Std. Arabic); dialectal pl. *qṣābī*) is usually rendered as castle, fort, fortress, château, or citadel – terms that in their own cultural setting are fully as generic as *qasba*. Such terms, however, evoke images and institutional frameworks (European, medieval and feudal) that do not really suit *qasba*-s. The mystique and appeal of *qasba*-s is a product of the same colonial-era art and literature that popularized the blanket use of *qasba* to label fortified places in the Maghrib (western North Africa) rather indiscriminately. The usage and the associated romantic flavor spilled over into nineteenth- and twentieth-century European historiography and anthropology.

In Arabic sources going back to the third AH/CE eighth century to seventh AH/CE thirteenth century, the fortification terms *ḥiṣn*, *qaṣr*, *qal'a*, and *ma'qil* (refuge, base) are far more common than *qasba* (Benhima, 2008). Moreover, if and when used, *qasba* often conveyed specific nuances: (a) keep, as core (*jawf*) of a fortification (the command post and residence), and (b) the political and economic central place of an area, a collective space. The latter sense resonates in the pre-Saharan Maghrib to this day, even though meanings have shifted compared to what they were before c. 1600 CE: *qasba* now tends to denote a private elite residence with quarters for a retinue/garrison, while the defensible collective and economic space usually is a fortified village, a *qaṣr* (*ksar*, pl. *ksour*).

The term *qasba* as commonly used and misused covers a wide range of structures differing in design, building materials, structural engineering, topographic setting, and date of origin. At one end of the spectrum, we find walled encampments (*amṣār*, sing. *miṣr*) (mostly long destroyed, overlaid by later works, or absorbed

into urban fabric), palace precincts, or urban citadels (freestanding or tied into the defenses). At the other end, *qasba*-s comprise modest local forts, the fortified habitat of kin groups, collective emergency refuges, fortified granaries shared by multiple stakeholders under customary law, and even old caravan way station enclosures (*nzāla*-s) maintained by local lineages as guarantors of travelers' safety. The array of *qasba* types does not represent, however, any straightforward sequence from "primitive" to "advanced." Regardless of date, different kinds of *qasba*-s were adapted to needs, means, and context.

Qasba-s are not easily reduced to a military dimension alone. They fulfilled diverse political, socioeconomic, ideological, propagandistic, and socially differentiating functions. Military aspects were intertwined with the other ones often, but not always. The *qasba* as a palatial precinct, even when designed as a fortification or nestled inside outer defenses, was laid out to stage the ceremonial discourse of power. *Qasba* quarters welded to or embedded in historic town cores (*médinas*) constitute a later development. Almost any type of *qasba* – if urban, large enough, and eventually overrun by private or kin group houses forced into high-density patterns by constraining fortifications – could give rise to a *qasba* quarter. Parallel urbanization during the colonial/Protectorate period (*médina* complemented by a separate *ville nouvelle*/colonial town) – a conservation-minded process but also one imbued with colonial ideology – favored the persistence of *médina/qasba* pairs in the Maghrib.

In various well-preserved Maghribī *qasba*-s, the visually dominant parts often date to c. 906 AH/CE 1500 and later. Key components range from Sa'did or 'Alawid (Morocco) and Ḥafṣid (Tunisia and Algeria) to Ottoman (across the Maghrib). At coastal locations formerly occupied by Europeans, mainly in the sixteenth century, prominent elements tend to be Portuguese (Morocco) or Spanish (Morocco, Algeria, Tunisia). Remnants of pre-1500 CE walls, gates, or towers may be embedded deep within later works (e.g., at Ceuta or Safi) – an aspect highlighted especially in recent historical and archaeological

Qasba in the Maghrib, Fig. 1 The *qasba* of Agadir from the air, before its destruction in 1960 (View adapted and enhanced from an early colonial-era photograph)

research (Ceuta or Tangier) (Elbl, 2012). Some seventeenth- to nineteenth-century *qasba*-s or associated defenses were partly designed by hired foreign experts, mostly European or Ottoman, e.g., at Essaouira (Mogador/Amagdūl (Morocco), basic layout by Théodore Cornut, 1764) or at Agadir (Morocco) (hilltop *qasba* destroyed in 1960 by earthquake) (Fig. 1).

Extensive gaps remain in data regarding Maghribī *qasba*-s. Closely related settlement patterns, auxiliary defensive systems, and hydraulic installations, especially those dating to the immediately pre-Islamic and early Islamic periods (late sixth century CE to the early fourth AH/CE mid-tenth century), have not been explored in detail. This affects our comprehension of the dynamics of past land use, the politics of water, community organization, landscape change, and collective defense (Benhima, 2008). This is especially true in Algeria, in eastern Morocco, along the pre-Saharan desert edge, and also at various oases west of the Fazzān region of southwest Libya. One of the exceptions is the old urban core of Sijilmāsa, to which al-Muqaddasī, for

instance, referred as *qasabat al-bilād* (i.e., the central place or *qā'ida*) of its district (Tafilālt oasis, southern Morocco; key archaeological campaigns from 1988 to 1998) (Messier, 1997a) (Figs. 2 and 3).

Qasba as a Spatiotemporally Hybrid Concept

What stands out readily for most observers is the contrast between *qasba* as a citadel or a palace/administrative precinct, the size of an urban quarter, and “kasba(h)” as the fortified village or collective granary (a *qṣar*, *agadīr*, or *ighrem*) that constitutes a widely recognized identity icon of pre-Saharan Morocco (Nijst, Kasba 64 Study Group, et al., 1973). This icon has now become a hospitality industry marketing tool, in the shape of neo-kasbah and post-kasbah pastiches designed to hint at Amazigh (Berber) heritage (e.g., the ecolodge Atlas Kasbah in the Sūs). The kasba(h) is commonly associated with the use of *ṭābiya* (replaced by concrete in modern

imitations), unbaked brick (adobe), and mixed materials. This style confronts the traveler mainly in parts of the western High Atlas, along the pre-Saharan slopes of the Middle Atlas and eastern High Atlas, in the eastern Anti-Atlas, the Siroua, the Dadès, the Dar'a Valley, and the Tafilālt. Even in these areas, however, and certainly elsewhere, competing and less publicized fortifications feature dry stone or rubble masonry (as did various Almoravid *qaṣba*-s).

The indiscriminate use of *qaṣba*/kasba(h) to designate disparate defensive structures is relatively recent. By the late 1930s the attention of the public and of colonial/Protectorate authorities was being drawn to the “kasba berbère” of the Dadès and Dar'a valleys as an architectural type, to the “route des kasbas” as a tourist itinerary, and to the area from Ouarzazate to Kelaa Mgouna as a heritage zone, in order to fund the exploration of Amazigh architecture (Terrasse, 1938 (2010)). An earlier trend, from the 1850s onward, had seen various *qā'id*-s of the Moroccan *makhzen* and later on *qā'id*-s cooperating with France to label their bases kasba(h) – i.e., *chef-lieu*, central place. The two trends blended, and the term kasba(h) spread to the settlements of various *amghar* (leaders) and kin groups. For the casual visitor, the *Amazigh ighrem* (dim. *tighremt*) and *agadīr* (pl. *igudār*) thus became a romanticized kasba(h). A similar drift affected functionally equivalent structures – the Rīfī *aqrār* (or *hrī*), the *guella* (*guela'a*, *gual'a*) (Algeria (Aurès)), and the *gṣar* or *ksar* (pl. *gṣūr*, *ksour*) of southern Tunisia and Tripolitania (De Meulemeester, 2003). The trend proved enduring. In Morocco, new rural heritage surveys (1980s to present) started by showcasing the iconic kasbas and ksour of the south.

The *qaṣba*/kasba(h) dichotomy was compounded, from the late 1970s, by critical study of historic settlement patterns and organization of rural space in al-Andalūs and in the early Islamic Mashriq (East). Research relating to the Maghrib lagged by comparison (Cressier, 1995). Conceptual filters focusing on al-Andalūs, readily available and methodologically more advanced in the 1980s, were thus prone to obscure the Maghribī specifics of terms such as *qaṣba*, *hiṣn* (a larger freestanding fortification

dominating interlaced rural settlements (*qarya*-s)), *qal'a* (usually a mountain fortress), *ṣakhra* (or *ṣukhayra*, mostly a collective refuge, often on a naturally defensible crag), *burj* (detached auxiliary fort or redoubt), and *ṭālī'a*, *nāḏūr* (dial. *nāḏūr*) (watch tower), or *maḥras* (pl. *maḥāris*) (a blockhouse with observation post). The ambiguities were aggravated by the fact that historic derivatives of *qaṣba* in Iberian languages – *alcazaba* and *alcáçova* – had drifted their own way, over centuries, entrenching definitions and concepts that did not necessarily match Maghribī situations.

The Origins of the *Qaṣba*

Local solutions, technological borrowing, invention, and adaptation intersect in *qaṣba*-s. Reassessments of the “siècles obscurs” (dark ages) of Maghribī history (fifth to ninth centuries CE) suggest that Late Antique and Byzantine defenses, bearing an imprint of emergencies and already incorporating salvaged materials, represent one of the inputs. Another strand was local Late Antique and subsequent nucleation: the shift to compact fortified rural settlements that altered parts of Roman Africa's landscape of open farms and large export-oriented estates (Fenwick, 2013). The third strand presaged the *qaṣba* as *extra muros* walled camp (a *miṣr* or *maḥalla* (Berber *āfrāg* or *tagrārt*)) or the inner core of such a camp. The type emerges by the second AH/CE eighth century, e.g., at Walīla (Volubilis (Morocco)), as a segregated settlement for eastern (not always Arab) newcomers (Fentress & Limane, 2010). Such *miṣr*-s reflect the parallel urbanization documented in the Mashriq from as early as 29 AH/CE 650, e.g., at Byzantine Aila/Umayyad Ayla in the Gulf of 'Aqaba or at the twice-besieged Sāsānian Iṣṭakhr in the Fārs (Iran) (23 AH/CE 643–29 AH/CE 649–50) (Martínez Enamorado & García Alfonso, 2002). The fourth strand was palace/administrative precincts insulating key power players from the urban populace and from the fractious Arabo-Persian *jund* military. The trend is highlighted in Ifrīqiya (Tunisia) by 185 AH/CE 801, with the founding by *amīr*

Qasba in the Maghrib,

Fig. 4 The Byzantine walls of Tebessa in the later nineteenth century. Note the reuse of salvaged components, such as drum sections of columns (Early photograph (c. 1850–1890))

Ibrahīm b. al-Aghlab of the *al-‘Abbāsīya* precinct south of Kairouan (Qayrawān). Later precincts, nearby, presaged the model’s persistence: Aghlabid *Raqqāda* (263 AH/CE 876) and Fāṭimid *Ṣabra al-Manṣūrīya* (337 AH/CE 948–9) (Cressier & Rammah, 2006; Martínez Enamorado & García Alfonso, 2002).

In the case of *qaṣba* as camp, fortress, or palace precinct, layouts defined or inspired by local Late Antique and Byzantine works at first meshed with equally culturally mixed Umayyad models from the east. These blended later on with ‘Abbāsīd architectural formulas (Martínez Enamorado & García Alfonso, 2002). Texts as well as archaeology suggest that many of the urban sites in Paul-Louis Cambuzat’s mid-1980s study of seventh AH/CE eleventh century Ifrīqiya incorporated Byzantine forts later held by Muslim garrisons (Cambuzat, 1986). Solid evidence for continuity comes, e.g., from Tocrā (Taucheira) in coastal Cyrenaica, where a Byzantine emergency intramural fort, basically a *qaṣba*, was built ca. 21 AH/CE 642. After Tocrā’s capitulation in 23 AH/CE 644, the fort remained in use, only with a new garrison. Similar reuse is attested at Ksar Lemsā, Haïdra, Béja, Tebessa, Jaloula, Zana, Tigisis, Ksar Belezma, Bagai, Tobna, at the Aghlabid Burj Younga, and elsewhere. How one should interpret fortified forums, amphitheaters, and small seventh- to ninth-century CE forts at town not walled during the Byzantine era, such

as Sbeïtla (Sufetula) – whether as discrete *quṣūr* or as *qaṣba*-s – remains debatable (Fenwick, 2013; Martínez Enamorado & García Alfonso, 2002; (Fig. 4).

The rural evidence is even more complex. Private fortified estates (*centenarium*, *turris*) prevailed, for instance, in Tripolitania (e.g., Jabal Tarhūna and the Sahara edge) after the decommissioning of the forward Severan *limes* in 259–63 CE. From the fourth century CE – a period blighted by early Christian sectarian strife – settlements clustered around redoubts resembling later *quṣūr* (sing. *qaṣr*, vernac. *ksar*). The outermost perimeter might be fortified, forming a kind of *ḥiṣn* around the core/*qaṣba*. The process is assumed to reflect a shift from dominance by great Roman-era landowners to a more socially flat organization, with control of agriculture and of desert trade by local lineages and long-entrenched Amazigh populations (e.g., the Luwāta or the Infūsen in Tripolitania). At present, confirmation is lacking for a general hiatus between such settlements and the second to third AH/CE ninth to tenth century expansion of villages and tower granaries, many of them newly founded. A notable obstacle to the dating of sites is the imperfect sequence of seventh to ninth-century ceramics (Benabbès, 2005; Fenwick, 2013).

The founding of *ribāt*-s intended to boost coastal defense and communications in Ifrīqiya

(Tunisia) before and after c. 184 AH/CE 800 (i.e., before and after the establishment of the hereditary Aghlabid governorate) blurs the origins of *qaṣba*-s further. Just like *qaṣba* could partly be a function and not so much a thing, so *ribāṭ* too was a function: at first a plain guard post, squad (*rābiṭa*) base, or staging point for cavalry, it was not necessarily wrapped in the shroud of prestige associated with holy war. Early sources refer to the prominent *ribāṭ* of Monastir (Munastīr (Tunisia), founded (180 AH/CE 796) as a *ḥiṣn*, a *qaṣr ribāṭ*, or *qaṣr li-l ribāṭ* – a humble fort serving *ribāṭ* purposes (Khalilieh, 1999). Functions and structures accreted through time. Several *quṣūr* were added to the Monastir *ribāṭ* by c. 973 CE, and the whole, enclosed in a larger enceinte, was now a citadel (*ḥiṣn*) comprising discrete *qaṣba*-s (*qiṣāb*). Tactical nesting thus marked *qaṣba* design and terminology from early on.

Qaṣba Patterns: General Observations

No adequate model of a typical *qaṣba* exists, mainly because of the wide range of types. The most frequently evoked characteristics reflect (a) research relating to al-Andalūs (Cressier, 1995), (b) Jean-Claude Garcin's post-eleventh century and explicitly pan-Mediterranean concept of the “ville des cavaliers” (horsemen's town) (Garcin, 2000), and (c) constructs such as André Raymond's contrast between a tactically closed private (upper) town or quarter and tactically open public (lower) town or quarter (Raymond, 1984). Viewed through this filter, a *qaṣba* (or *qal'a*) is a citadel dominating an urban core (*madīna*). The two are so interrelated that one seems unthinkable without the other. Inside the *qaṣba*, the palace/keep (ostensible site of legitimate power (*al-mulk*)) and other elite establishments may rank as *quṣūr*. Stables (*riwā*, pl. *arwiya*, vernac. *rwīya*, *rwāyāt*; western equivalent of the Mashriqī *iṣṭabl*) are typically adjacent to or part of the *qaṣr* nucleus. A large open space for ceremony and for cavalry exercises – the *maidān* (pl. *mayādīn*) – tends to buffer *qaṣba* from *madīna*, functionally evoking

a Late Antique/Byzantine hippodrome, just like the *qaṣba* and its core *qaṣr* faintly evoke a Roman camp with its *praetorium* or *principia*. Andalūsī usage suggests that if ranking as a seat of *mulk* – a casa real/crown residence – the entire *qaṣba* might take the label *qaṣr* (Sp. *alcázar*) to denote political status. In such a case, lesser (often earlier) inner precincts became *qaṣba*-s – quite properly, given the term's range of meanings (Martínez Enamorado & García Alfonso, 2002). This tentative model does not fit all settings, however, and is rather static.

There was a variation in what came first – core keep or outer enceinte – unless a preexisting *madīna* constrained choices. The first stand-alone *ribāṭ* at Monastir (180 AH/CE 796), for instance, devolved into a *qaṣba* inside a larger *ḥiṣn* only by the later tenth century CE. At al-'Abbāsīya (Kairouan), the *Qaṣr al-qadīm* (or *Qaṣr al-abyaḍ* (185 AH/CE 801)) – the core (*qaṣba*) of the Aghlabid precinct – was built first. Surrounding cantonment and enceinte followed. Similarly, most parts of 'Ubayd Allāh al-Mahdī's Fāṭimid *ḥiṣn* of Mahdiya (Tunisia) (isthmus barrier wall, enceinte, and two palaces/*quṣūr*) were built in a coherent building push, even though it lasted a decade (300 AH/CE 912 to 308 AH/CE 921). Inside the initial Almoravid camp at the future site of Marrakech (1060s AD), however, the *Dār al-Ḥajar* (the Stone House *qaṣba*, c. 463 AH/CE 1070) was set up first. A town enceinte had to wait until c. 520 AH/CE 1126.

Construction sequences at the partially excavated Qal'at Banī Ḥammād (Hodna, Algeria; founded 398 AH/CE 1007–8) are still not clear (Bourouiba, 1975). The *qaṣba*-like enclosure that comprises segments of a Roman wall, the *Qaṣr al-Manār* palace, and the signals *burj* may have been the original core. A nearby simple mountain refuge, Kiyāna, preceded it, dating back to the 332 AH/CE 943 Khārijī revolt of Abū Yazīd, the *ṣāhib al ḥimār* (Man on a Donkey). At Rabat (Ribāṭ al-Faṭḥ), an Almohad *qaṣba* furnished the first core (built 545 AH/CE 1151, under 'Abd al-Mu'min), holding inside its c. 4 ha a fort/palace (*qaṣr*) and a *khuṭba* mosque, among others. Documented use of adjacent terrain to lodge troops bound for al-Andalūs followed only in

560 AH/CE 1165. Walls enclosing a large *maḥalla/ribāṭ* area and suitable for a proper *madīna* were started only in 566 AH/CE 1171 under Abū Ya'qūb Yūsuf b. 'Abd al-Mu'min and completed under Abū Yūsuf Ya'qūb al-Manṣūr (1184–1199 CE). (Sedra, 2008). At quickly built new Marīnid strategic camp towns such as *Āfrāg* (1328 CE), outside of Ceuta, enceinte and embedded *qaṣba/qaṣr* rose mostly in tandem (Villada Paredes & Gurriarán Daza, 2013), but at organically developing towns such as ninth- to thirteenth-century Tunis, the *madīna* enceinte and successive *qaṣba*-s and palaces/*quṣūr* sought adjustment to each other over centuries.

It was not only spatial and chronological nesting as both design and process that patterned the history of *qaṣba*-s. Parallel urbanization did its share, as did the serial founding of new palace/administrative precincts to mark the rise of new dynasties and their altered political order. The gesture of forsaking, even ruining, earlier rival sites often went hand in hand with new *qaṣba* construction. Salvage of materials was common. To this we must add other pattern-setting determinants, at least in terms of location choice: coastal defense, surveillance of trade and military arteries, creation of strategic reserves, and segregation of rivals, of dissidents, and of outlying or rugged-terrain districts difficult to control fully. These factors relate mostly to *qaṣba* building by an established or rising central regime. Other dynamics at regional and lineage level shaped the number and location of rural *qaṣba* refuges, granaries, and staging posts along trade or seasonal migration corridors habitually claimed by diversified lineage groups (Acién & Cressier, 2009; Benhima, 2008).

Historic towns with a complex past, e.g., Marrakech, Fez, Meknès, Tlemcen, Algiers, Bône, Bougie, or Tunis, embody long sequences of the relevant patterns. At Meknès (Miknās al-Zaytūn) (Morocco), early settlements such as Qaṣr Tūrziḡuīn were complemented by an Almoravid *tāgrārt* (a *maḥalla* enclave dubbed a *hiṣn*), with at least one *qaṣba* nucleus. The extent of Tāgrārt's reuse by the Almohads is unclear (by the 1190s AD, some twelve new *quṣūr*, military and residential, some with *qaṣba*-like enclosures of their

own, were dotted around Tāgrārt, now a *madīna*). After the final Marīnid takeover (645 AH/CE 1247–8), a separate new *qaṣba* was built under Abū Yūsuf Ya'qūb (from 674 AH/CE 1276) (El Khammar, 2005). Under Mawlāy Ismā'īl (1082–1139 AH/CE 1672–1727), components of the Almoravid and Almohad *qaṣba*-s embedded in the *madīna* were remodeled, and the Marīnid *qaṣba* largely razed to create a palace precinct with spacious gardens, structured around the *quṣūr* of Dār al-Kbīra, Dār al-Madrasa, and Qaṣr al-Mhansa. Lesser *qaṣba*-s were scattered around the *médina* proper (Hadrās, Barrīma, Sīdī Sa'īd, Gnāh al-Aman and Qā' Warda) (Barrucand, 1985; El Khammar, 2005). Numerous decorative components were extracted from the opulent sixteenth-century Sa'did *qaṣba* of Marrakech (*Qaṣr al-Badī'*, 1002 AH/CE 1578–1593), plundered and almost entirely dismantled by AH/CE 1698–1119 AH/CE 1707.

At Tlemcen (Algeria) a similar sequence presents itself. The small Roman colony of Pomaria grew in c. 122 AH/CE 749–AH/CE 950–967 into a roughly rectangular Amazigh *maḥalla*-type settlement (Agadir) with a *qaṣba* in the southwest corner. In 473–4 AH/CE 1081–2, a separate Almoravid *tāgrārt* sprang up west of Agadir, at first only a large empty *hiṣn* with a *qaṣba* core (Qaṣr al-Qadīm), like at Meknès or at the stone-and-brick Almoravid *qaṣba* atop Jbel Amargū (Amargō (Amargou), 50 km northwest of Fez; reused as late as the 1270s CE). The Almohads created around 540 AH/CE 1145 a separate precinct (a palace/*qaṣba*) in the area of the later Mashwar citadel. Agadir and Tāgrārt fused into a dual fortified town by 581 AH/CE 1185 (main enceinte construction under 'Abd al-Mu'min), and Tāgrārt had become the upscale administrative sector (Dahmani, 1983). The Marīnid Long Siege of Tlemcen (699–707 AH/CE 1299–1307) saw the founding of a third separate *maḥalla* called *al-Manṣūra*, a town-size camp 2 km west of Tāgrārt, with a palatial *qaṣr/qaṣba*, *khuṭba* mosque, hospitals, baths, markets, and caravan-serais. Ruined in 1307 CE, *al-Manṣūra* was rebuilt in 1337–1344 and ruined again in 1348 and 1361. The old Mashwar *qaṣba* was repurposed as an 'Abd al-Wadid residential *qaṣr*

Qasba in the Maghrib, Fig. 5 Partial view from within the ruined Marīnid *maḥalla* of *al-Manṣūra*, showing the state of structures next to the minaret in the late nineteenth century (c. 1860–1890). A remnant of fosse runs around

the corner and along one side of this block. Most of the walls, with the exception of the minaret, are made of *ṭābiya* erected on rubble masonry foundations (Early photograph)

Qasba in the Maghrib, Fig. 6 The Mashwar of Tlemcen in the nineteenth century (Lithograph from a sketch by Genet, 1836)

(633–81 AH/CE 1236–83) and later adapted for use as *qaṣba* once again by *ghulām/oghlan* (Kouloughli) Turkish troops (after 962 AH/CE 1555) (Figs. 5 and 6).

At Fez, the commonly cited sequence starts with the dual eighth- to ninth-century CE settlements of Fās and al-'Āliya (the latter became the al-Qarawiyyīn quarter), each with their own *qaṣba*, defensively flanked by other forts.

The two urban cores were amalgamated under the Almoravids and to the west a new *qaṣba* was built at Bū Julūd (*Qaṣba al-Filāla*). Torn down (540–1 AH/CE 1145–6) and rebuilt by the Almohads, the Bū Julūd *qaṣba* was then reused by the rising Marīnid dynasty, at first, only to be supplanted by a new Marīnid palace/administrative precinct even further west, laid out in 674 AH/CE 1276 – al-Madīnat al-Bayḍā' or Fās

Qasba in the Maghrib,

Fig. 7 Main entrance to the Ismāʿīlian *qasba* at El 'Aioun Sidi Mellouk (1679 CE) on the road from Oujda to Taza. Under Mawḷāy Ismāʿīl it held a garrison of 500 Zirāra cavalry and was under the orders of regional headquarters at Oujda. State of the structure c. 1914–20. Note the more modern service sheds lining the walls. Early colonial-era photograph in the author's collection

al-Jadīd. In the sixteenth century CE, this *qasba* was reinforced with artillery emplacements (Barrucand, 1980). Other instances of spatiotemporal drift in the location of urban *qasba*-s can be found at Taza (Morocco) and Bougie (Bijāya) (Algeria) or Tunis. Nineteenth- and early twentieth-century sources document similar patterns for rural *qasba*-s, particularly in Morocco. Time and again ruins of old *qasba*-s, sometimes in serial clusters reaching back through time, are mentioned close to recently built fortifications (1850s–1910s).

For many rural *qasba*-s, encompassing micro-regional contexts based on both historic and archaeological data remain to be established. This applies, for instance, even to the c. 80 listed and for the most part well-identified government *qasba*-s built or restored in Morocco under Mawḷāy Ismāʿīl (1082–1139 AH/CE 1672–1727) (Chapelle, Lt. F. de la, 1931) (Fig. 8). Collective rural defenses are often lumped by the dozen in the sources, in clusters located simply by subregion, mountain range, or lineage territory – thus the cluster of *Qulūʾ Jāra* in the Rīf of the Banī Wartadī, the *ḥuṣūn Waṭṭāṭ* on the Moulouya taken by the Almoravids in 463 AH/CE 1070–71, even more generically the Moulouya *ḥuṣūn* taken by the Almohads under ʿAbd al-Muʿmin, the *ḥuṣūn* of the Ghumāra, those of the Taza area, those of the Sūs and the Tafīlālt, the *quṣūr* of the Maṣmūda around Aghmat (Benhima, 2008), and so on all the way

east to Ifrīqiya and southeast into the Tuat and Gourara (Tigurārīn) (Sahara). By contrast, fortifications built by successful centralist regimes during their rise as well as in decline stand out more distinctly as individual structures, in the sources as well as in the emergent archaeological record. The lists of such *qasba*-s are not always reliable, however. They often bear the imprint of propagandistic narratives of dynastic origins (e.g., al-Baydhaq's list of Almoravid forts built to contain the rising Almohad movement) (Benhima, 2008) (Figs. 7 and 8).

Qasba Research and Heritage Issues

As of March 2014 no unified, open access spatiotemporal GIS database was available that would cover all known Maghribī *qasba*-s and related or precursor sites from Late Antiquity to the colonial/Protectorate period. Even in compact areas such as the Rif (northern Morocco), for instance, site data remain to be refined. Surveys in the Rif and in adjacent areas since the late 1970s and then more systematically from 2000 onward, accompanied by targeted excavations at Bādīs, Nakūr, Maṣṭāsa (a *qasba*/hilltop refuge, Jbel Tiroubai), and al-Mazamma (2010) (Project PAC Rif central), have established a baseline (Cressier, 1981–1982; Touri, Bazzana, & Cressier, 1988). More work, however, needs to be done. The historic context is reasonably clear at certain sites,

Qasba in the Maghrib, Fig. 8 Spatial distribution of key well-documented Ismā'īlian *qasba*-s. The map represents a recent snapshot from an evolving GIS database

whose underlying core was originally constructed around raw data in Chapelle and assorted colonial travel sources (Chapelle 1931) (Cartographic rendering by author)

such as the Marīnid *qasba* of Tāzūṭa (pre-1213 AD-1293 AD; reused in the sixteenth century), the Marīnid *qasba* at Debdou, the Dār Sulṭān *qasba* at Targha, or the Ismā'īlian *qasba*-s of Seluan and Snāda (the latter replacing an earlier Sa'did *qasba*) (Barrucand, 1980; Cressier, 1981–1982; El Boudjay, 1996). Elsewhere, puzzles remain: the small artillery *qasba/burj* on the beach of Targha (deemed to be Sa'did), the hilltop ruined fortified village (thirteenth century CE or earlier) and European-style fort at *Qal'at Sanhāja/Torres de Alcalá* (El Boudjay, 2003), or the enceinte fragments of Sūr al-Qasaba at the Iharounen-Boukrat confluence (El Boudjay, 1996) (Fig. 9).

Prominent urban *qasba*-s are covered quite extensively in the literature, but gaps persist. Conservation and meaningful integration into

Qasba in the Maghrib, Fig. 9 Marīnid *qasba* of Debdou. Corner tower and section of main curtain with a large swath of weather sealant topcoat still partly in place. All sections shown are ṭābiya on stone rubble foundations

modernizing urban textures progressed rapidly in 2000–2013, but whether or not a *médina* with its *qaṣba*(s) figures on the UNESCO World Heritage Site list is not always an indicator of satisfactory solutions. A case in point is the *qaṣba* of Algiers, listed since 1992 – or more specifically the top part of the historic upper *casbah* (al-Gabal (*Jabal*)) (the lower town or the *Quartier de la Marine* (*Quartier de l’Ancienne Préfecture*)) had changed drastically starting in 1830–1849). After the serial crises affecting the *qaṣba* ever since the 1931 colonial urbanistic blueprint and the stalled projects that followed, a thorough new plan was tabled in 2011, but the *qaṣba* remains a fragile environment in 2014. A fundamental salvage archaeology project in the Place des Martyrs area started in 2009, spurred on by subway (Métro) construction. In general, it remains difficult to model trends in the role and evolution of urban *qaṣba*-s throughout Maghribī history or to present them to the public as de-romanticized and properly contextualized components of *médina* architecture. The tourist appeal of the *qaṣba*/kasbah concept continues unabated. Redevelopment and gentrification driven by cultural tourism have entered a new phase since c. 2003 with a proliferation of authentic *riad*/*maison d’hôte* hotels and residences (Elbl, 2013) (Fig. 10).

The rural *qaṣba* has become a factor in new approaches to writing Maghribī history, even though archaeology of the fortified rural habitat lags behind. As Yassir Benhima stressed (2000, 2008), without studies of rural defenses, in context, it is difficult to decode past regional patterns of climate change, landscape evolution, land use, demographics, shifts between transhumance and sedentarization, rural vs. urban dynamics, and, ultimately, state formation and its failures. The issues go beyond inventorying and excavating discrete sites. A broadly based archaeology of the *qaṣba* can potentially become a tool to cut through biases embedded in the written sources of Maghribī history – above all in propagandistic narratives of dynastic origins or of social and political movements. It offers a valuable auxiliary key to sources ranging from al-Muqaddasī (aka al-Bashshārī) and Ibn Ḥawqal to al-Bakrī, al-Baydhaq, *al-sharīf* al-Idrīsī, the anonymous

Qasba in the Maghrib, Fig. 10 View of a steeply sloping street in the *qaṣba* of Algiers, nineteenth century (c. 1870–1895). Upper floors on timber structural supports extend into the airspace above the street. Minimal street width was typically governed by custom, precedent (in principle, seven cubits (c. 3.5 m) for a pedestrian passageway (*ṭarīq al-mushāl*)), and legal opinion – sometimes respected more in breach than in observance, depending on circumstances

Kitāb al-istibṣār, and onward to Ibn Abī Zar‘a, Ibn Khaldūn, Leo Africanus, al-Nāṣir al-Salāwī, and colonial-era records.

On the conservation front, much has been achieved, thanks to dedicated individuals and institutions. In the Moroccan south, for instance, the thrust has been spearheaded by CERA (Centre d’Études et de Recherches Alaouites (Rissani, Tafilālt), key project: Ksar al-Fida, now the Musée archéologique et ethnographique de Sijilmasa-Tafilalt since 2003) and by architects and anthropologists like Salima Naji (e.g., the restoration of Aguelluy (2004–2006), Inoummar (2005), Amtoudi (2006–2008), Id Issa (2007), Ksar Assa (2006–), the 1810 CE Kasbah Aghenaj (2008–2011) (now the Museum of Tiznit), Aīt Kin (completed 2012–2013), Agadir n’Issergine (ongoing), and other sites) (Naji, 2006, 2013).

Qi

Steven Klarer and Ted J. Kaptchuk

In Chinese culture, *qi* is the common denominator that underlies all being and all behavior

and that allows for their interaction and their interpenetration. *Qi* enables seeds, air, and soil to become plants, a mountain range to produce good fortune, or a human being to cultivate wisdom and human kindness. It is what makes possible the processes of chemistry and the researches of the alchemists. *Qi* is the fundamental Chinese articulation of what underlies the universe, what is the universe, and what is the reality of the universe.

Given the key position the concept of *qi* holds in explaining the process of change in Chinese scientific, medical, psychological, and spiritual thought, one is tempted to assume that it is one of the oldest and most central concepts in the Chinese world view. A look at the history of both the character and the concept shows otherwise.

The oldest inscriptions in Chinese, the bones used in the Shang dynasty oracle, are concerned with understanding the process of change in such uncertain areas as agriculture and illness. Nowhere in the more than 200,000 known extant oracle bones can one find the character *qi* or anything which might be its close antecedent or relative. Throughout the oracle bone inscriptions we see that, in Shang culture, change was brought about by the actions of spirits rather than by naturalistic forces.

The character *qi* is composed of an element which signifies vapors which rise to form clouds and another element which means grain. The character may mean vapors arising from cooked food or simply steam. At this level of the character's history *qi* is a simple notion. *Qi* is what makes the lid on a pot of boiling water rattle.

In the course of its development Chinese thought began to look for the origins of change in sources other than the spirits. For a time change, especially illness, was understood to come from the winds of the eight directions, each of which was responsible for causing particular diseases at particular seasons and each of which was personified as a deity. Although this model of change brought about by wind is a step toward a world of naturalistic causality and away from a world of spirit causality, it still has a strong component of the latter. It is probably,

however, a major step in the development of the concept of *qi* which later comes to permeate all of Chinese thought.

By the time of Confucius (551–479 BCE), the word *qi* appears in literature but it is rare and its meaning is confined to purely human qualities. The *Analects*, the record of Confucius' teachings, use the word four times, each of which is distinctly related to some aspect of human behavior, such as appetite, tone of voice, breath, and physical stamina. In none of these does it refer to anything beyond a specific physical quality of human life. At this stage in its history *qi* still shows its origin as a common, ordinary term.

The several centuries following Confucius were a critical time of change in Chinese culture. One of the key concepts to emerge at this time was *qi*. Mencius (371–289 BCE), the follower of Confucius, refers to *qi* 19 times and each time it is a concept of major philosophical import. *Zhangzi*, between 399 and 295 BCE, a major Daoist text, refers even more frequently to *qi*. In this text we see one of the earliest and clearest uses of *qi* to refer to a natural force, something which, although an attribute of human beings, is also a power which makes things happen in the world. We see this conceptualization of *qi* (although still connected to wind) as a moving power in the universe in a famous passage from the *Zhangzi*.

The great clod belches out breath (*qi*) and its name is wind. So long as it doesn't come forth nothing happens, but when it does, the 10,000 hollows begin crying wildly.

Here *qi* is a conceptual model for explaining and understanding the process of change in the observable world. The Shang world of a supernatural spirit causality which had developed into the world of semisupernatural wind causality has now become a world of natural causality. The *qi* model explains the process of change and development in a naturalistic way which is conducive to the expansion of philosophic and scientific thought and inquiry.

By the late third century BCE we see *qi* becoming a concept used throughout Chinese thought. This conceptualization/experiential

model is used to explain the qualities of plants and animals, the uses of herbs, and the influences of climate, weather, and geographic location on people. From its use to explain the process of disease and illness comes psychological insights into character and personality types. Eventually, through philosophers such as Wang Yangming (1472–1529), *qi* becomes an essential quality which enables all change since, no matter how they seem to differ, all things share the same *qi*. It also becomes a moral spiritual quality allowing for the oneness of all being.

In recent times, possibly under the influence of Western thought, *qi* has frequently been identified with the Western concept of energy. Westerners are by no means the only ones to make this equation. To characterize *qi* as energy is to invoke a worldview which the Chinese never had, a worldview in which matter and energy are different things. While it is true that modern scientific theory no longer holds that matter and energy are separate entities the words have come, through several centuries of use, to connote, in common parlance, distinct, and separate entities. To the Chinese matter was never inert; it always had dynamic and teleological properties.

As Western concepts of physics have caused some to think of *qi* as energy, nineteenth century western concepts of vitalism have caused it to be identified, especially in medicine, as some form of vital force, distinguishing living things. Historically, however, *qi* has been as much an attribute of a rock or river as of a person or animal. To call *qi* energy or life force is as erroneous as it is to call it matter. It is all and it is neither. *Qi* is the fundamental Chinese articulation of the interconnectedness of the universe, of what the Chinese call the 10,000 things. *Qi* is the cause, process, and outcome of all activity in the cosmos.

Qianjin Yaofang

Richard Bertschinger

The *Qianjin Yaofang* (Remedies Worth their Weight in Gold), and its sequel the *Qianjin Yifang* (More Remedies Worth their Weight in Gold), were written by the physician and alchemist Sun Simiao (also called ► [Sun Simo](#)) in 652 and 682, respectively, during China's Tang dynasty.

These books are especially valuable for the breadth of their content. They described the medicine of the day, both the systematic acupuncture and herbal tradition, and the less organized folk tradition. Unfortunately neither has as yet been translated into a Western language.

Sun built on the work of Zhang Zhongjing's earlier ► [Shanghan Lun](#), especially in advocating the careful selection, picking and preparation of herbs. In acupuncture he devised the system of *ahshi!* (ow! that's it!) points, or needling at the tender muscle nodules. These books also contained the author's newly verified and drawn charts of the channels and points on the body, with front, side, and back views – the earliest-known point charts to have been produced. The 12 channels were shown in five colors, while the eight extraneous channels were depicted in green.

Many of Sun's ideas were closer to Western notions of common sense. For instance he put disease down more to incorrect diet than to the influence of evil ghosts and spirits. He advocated general cleanliness to protect against the development of sores and ulcers, and he urged rinsing the mouth out several times after a meal to keep the teeth healthy and the breath fresh. During childbirth he said not more than two or three people should be allowed into the delivery room, to keep the mother quiet and the atmosphere calm, and he excluded anyone who had recently survived a fatal illness. He thus showed an awareness of complications arising in labor through the nervousness of the mother, and of infection spreading to the mother or newborn child. He also advocated the use of gentle

exercise in imitation of animals in order to prevent disease and combat the process of aging. He introduced the treatment of night-blindness with goat or ox liver (which is rich in Vitamin A), the use of the thyroid glands of sheep or deer (equally rich in iodine) for a swollen thyroid, and abstaining from salt in cases of edema.

He innovated a clear ethical stance on medical practice, urging the doctor to be vigorous in investigating the disease and finding a suitable treatment. Many of his methods are in line with modern thinking. His work was equally valued in both Japan and Korea and works in these countries quote extensively from his tracts.

Qibla and Islamic Prayer Times

Mohammad Ilyas

Ṣalāt (prayer) is one of five pillars of Islam. Islam requires all adult sane, healthy, and able-bodied Muslims to perform five daily prayers. The corresponding time intervals are commonly known as "Islamic prayer times."

Muslims are enjoined to face the *Ka'ba* in Mecca during their prayers. It is believed that *Ka'ba*, the cubical shaped edifice, was built by the Prophet Abraham. The direction to the *Ka'ba* from a place is known as its *qibla* direction. Mosques are built with a clear pointer in the qibla direction. Knowledge of the qibla direction is also important for certain other acts, including the call to prayer (*Adhān*), the ritual slaughter of animals for food, and burial of the dead. Muslim astronomers from early times dealt with the

determination of the *qibla* and produced highly sophisticated trigonometric and geometric solutions.

The time intervals of the specified daily prayers are clearly specified. The intervals are exclusive of each other; the end of one time interval marks the beginning of the next. Besides regular prayers, there are supplementary prayers, and some of these follow specific time intervals. There are also certain periods of the day during which prayers are prohibited. All this reflects the need for a clear understanding of diurnal phenomena and the proper determination of the time of day. The way in which the various Islamic prayers are distributed throughout the day further emphasizes the treatment of day and night as a single time unit, in contrast to the practice of earlier civilizations in treating them separately. Also, the mutually exclusive time intervals for each regular prayer, which depend upon the specific (local) positions of the sun, introduced a new way of dividing the day.

The Islamic prayer times are so defined that they can be easily ascertained by observation on a clear day. However, under cloudy conditions, one has to resort to some sort of a time clock and mathematical computation. Since the performance of regular prayers within the specified time intervals is a most serious matter, advance determination of the intervals is of great importance. From the very beginning, Muslim scientists were engaged in mastering the techniques of positional and observational astronomy, including instrumentation, and went on to develop this and allied fields. It is not surprising to find that almost all major astronomical works during that period of 500 years incorporated a discussion relating to the Islamic prayer times, which came to be known as *ʿIlm al-mīqāt* or the times of “fixed positions” of the sun. Closely associated with the Islamic prayer times is the matter of determining the direction of Mecca. Elaborate tables showing the direction of the *Kaʿba* from different parts of the world became an integral part of Islamic astronomical works.

The demarcation of various time intervals is based on the guidelines contained in the *Qurʿān* and elaborations given in the *Ḥadīth* (Traditions)

of Prophet Muḥammad. Based on these, the time intervals were subsequently translated into more precise definitions by the theological jurists of the early centuries of Islam. Muslim astronomers helped to translate these into equivalent astronomical definitions.

In Islam, the day begins at sunset and the time for the first prayer (*maghrib*) begins after the sun has set. The second (*ʿishāʾ*) and third (*fajr*) prayers then follow, the latter ending before the sun begins to rise. The fourth prayer (*Zuḥr*) is performed after midday and is followed by the fifth and last obligatory prayer (*ʿaṣr*) in the afternoon. The optional prayers performed after midnight (*tahajjud*) and a little after sunrise (*chasht*) have special importance. The time durations during which the sun rises, sets, and crosses the local meridian are prohibited times and no prayers are generally allowed during these periods. Thus, one has to determine the various portions of the day in a sequential and somewhat symmetrical way.

As we know, the “true” solar day-length keeps changing through the seasons. Therefore, on a 24 h civil clock, the solar phenomena, such as midday and midnight, keep moving backward and forward. However, as the Islamic time intervals are related directly to the true natural (solar) phenomena and not to the day length, it simply boils down to the daily determination of the times of various astronomical phenomena according to whatever day-time system is used, e.g., time-hours or time-degrees would be equally applicable. This situation obviously laid down strong foundations for mathematical-dynamical astronomy. Also we can recognize that the “day-time” length depends upon the season and the latitude and varies from a winter minimum to a summer maximum. For Islamic fasting, which is done from dawn to sunset, some countries are favored (shortest duration) in one season and others in a different season. In Islam, this situation has been fully taken care of through the rotation of the Islamic (lunar) months through the seasons.

Muslim astronomers during the medieval period made considerable efforts to construct tables of Islamic prayer times according to the defined solar positions. The data on the solar

position (azimuth) at different altitudes was also used for observationally determining the direction of the *qibla*. It was important to present the prayer times in the form of basic universal tables which would remain unchanged over a long time. These tables could then be used through secondary and smaller tables which could be recomputed if necessary.

These tables were universal, since the Muslims used a purely lunar calendar independent of solar calendar dates. For each new day/date, one simply needed to ascertain the solar longitude by direct measurement or through the simultaneous measurement of positional parameters at meridian passage.

Muslim astronomers' interest in regulating daily time went beyond the determination of prayer times to include overall time measurement. Their tables contained information on various time parameters, such as length of daylight and duration of the fasting period (from morning twilight to sunset), auxiliary tables on various functions needed in computations, and special tables on parameters such as the solar azimuth and solar altitude in certain azimuths for use in *qibla* determination, besides supplementary information on such parameters as horizontal refraction. The prayer tables were generally produced with great computational skills and care and in a comprehensive way. A study of Cairo's tenth-century astronomer Ibn Yūnus' *Kitāb Ghayat al-intifa' fi ma'rifat al-da'ir wa-faḍlihi wa-l-samt min qibal al-irtifā'* (Very Useful Tables for Finding the Time since Sunrise, the Hour Angle, and the Solar Azimuth, from the Solar Altitude), one of the major *mīqāt* tables, shows that Ibn Yūnus' values were, in general, very carefully computed. The tabular works incorporating *ṣalāt* times and other auxiliary tables were prepared for various major localities of the Muslim world, such as Cairo, Mecca, Medinah, Jerusalem, Damascus, Tripoli, Aleppo, Tunis, Istanbul, Baghdad, and towns in West Africa, Andalusia and the Indian subcontinent. Later work by a Damascus astronomer, al-Khalīlī (fourteenth century), greatly expanded the dimension of *mīqāt* tables by latitude and longitude degree of the globe. David King's

comparison of al-Khalīlī's data with modern calculations shows his work to be remarkably accurate. Al-Khalīlī's tables may thus be considered to present the first global data set on the *qibla*.

We noted how, through the ingenious use of solar longitude, the Tables were made time-invariant and independent of the solar calendar, and the computational system was further expanded to determine the solar altitude for a specific solar azimuth, giving the direction to Mecca. In this way, an accurate astronomical method was developed to meet an additional need. The remarkable achievements in mathematical astronomy mark the high points of Islamic astronomy.

In the period after the introduction of the mechanical clock, a 24-equal-h civilian day took over from the 12-h daytime and 12-h nighttime day which had dominated civilian timekeeping systems well into the fourteenth century. Although Muslim scientists had started to utilize an Islamic equal hour day, the use of true solar time and sundials prevailed in non-European and Islamic countries for quite a while. The detailed tables of Islamic prayer times constructed for specific localities of the Muslim world in the early centuries have remained in effective use right into modern times.

We are aware that as we go toward the higher latitudes, the usual cycle of daylight, twilight, and night begins to change during certain parts of the year. First, the night gets shorter and shorter with the increasing latitude, until the evening twilight merges with the morning twilight. In other words, the clear distinction of the end of the evening twilight from the beginning (or end – depending how one looks at it) of morning twilight no longer exists, and the determination of times for the beginning of *ishā*, *fajr*, and fasting cannot be done through the conventional solar position basis. As one moves toward the higher latitudes, even the twilight period gets shorter, to the extent that the end of the day merges with the beginning of the day, so that the sun does not set (or rise) but remains continuously above the horizon. In a situation like this, with 24 h of daylight, how is one to determine the times of *fajr* and *maghrib* prayers and how is one to fast a “nonending

daylight” day? This is one of the questions that needs to be tackled within the theological rather than the scientific arena.

Qin Jiushao

Ulrich Libbrecht

Qin Jiushao is one of the few mathematicians in China of whom we have fairly detailed

biographical data, since he held subsequent positions in government administration. Although not mentioned in the biographies of the official Song dynasty historical annals, numerous references to Qin Jiushao can be found in local monographies or writings by his contemporaries.

Qin was in all probability born in 1202 in Puzhou (now Anyue in Sichuan province). In his youth he was commander of the “patriotic soldiers”, an armed force outside the regular military establishment, in his native place. In 1224–1225 his father was given an appointment in the capital of Southern Song, Hangzhou. In the preface to his ► [Shushu Jiuzhang](#) he says, “In my youth I was living in the capital, so that I was able to study in the Board of Astronomy; subsequently, I was instructed in mathematics by a recluse scholar.” According to analysis of his mathematical work he must have studied the *Jiuzhang suanshu*. In 1226 he was staying with his father in Tongchuan (now Santai in Sichuan province). When the Mongols began their conquest of Sichuan and destroyed its capital Chengdu in 1235, Qin was at the frontier as a military official.

According to his own preface it was during this period of distress that his mind went back to the mathematical studies started in his youth. He escaped calamities by going to the southeast. He was appointed subprefect in Qizhou (now Qichun in Hubei), where he behaved badly, causing a military revolt. Later he was appointed prefect in Hezhou (now Hexian in Anhui), where he was responsible for the salt trade and sold salt illegally to the people, so that he left the southeast as a rich man, settling in Huzhou in Zhejiang. In 1244, he was named Court Gentleman for Comprehensive Duty in the prefecture of Jiankang (now Nanjing in Jiangsu). After 3 months he resigned because of his mother’s death and returned to Huzhou. It was during this 3-year mourning period that he wrote his mathematical work, which appeared in 1247. As a consequence he was recommended to the throne on account of his calendrical science, and he was allowed to take part in the examinations. We can only suppose that something went wrong, as we find him as consultant of the Directorate of Military

Affairs in Jiankang from 1253 until 1259. However, after that he resigned and went back to his native place. He paid a visit to chancellor Jia Sidao, and he got an appointment as prefect of Qiongzhou (now Qiongsanxian) in far Hainan. But after a few months he had to leave Qiongzhou because he was impeached for corruption and exploitation of the people. He followed his friend Wu Qian, who was a naval officer in the district of Yin in Zhejiang, and in 1259 he was appointed assistant in the Court of the National Granaries there. Wu Qian subsequently became a minister, but when he was disgraced in 1260, chancellor Jia Sidao also collected data about Qin, and put him away in Meizhou (now Meixian in Guangdong), where he died in 1261 at the age of 60.

Quadrant

Richard P. Lorch

The quadrant is an instrument which was used for measuring angles and for making astronomical calculations. Apart from those for the accurate observation of altitude, known to us almost entirely from written descriptions, the quadrants of the Arabic Middle Ages were portable. They fall into three categories: those carrying a projection, or two-dimensional representation, of the celestial sphere (the imaginary sphere containing the stars and celestial circles); those designed for astronomical calculations; and horary quadrants, i.e., those used specifically for telling the time by the altitude of the Sun. Most have a thread fixed at the vertex carrying a movable bead for transferring distance from the vertex from one point of the instrument to another. Of the first type the best known is the astrolabe quadrant, invented before 1100. These are essentially the plate and rete of a standard astrolabe overlaid on one another. The motion of a star (or the Sun) is imitated by the motion of the bead, which has been set by putting it over the representation of the star, about the vertex. In the *shakkāzīya* plate associated with the name of 'Alī ibn Khalaf (eleventh-century Toledo) and taken over by al-Zarqāllu (Arzaquiel), celestial coordinates may be converted (e.g., ecliptical coordinates into equatorial) either by moving one projection over another or by using one twice and transferring one set of coordinates to the other by means of the thread and bead.

The second type of quadrant is closely related to graphical solutions of astronomical problems by ruler and compasses, the function of the compasses being taken over by the string and bead (or ruler) fixed at the vertex. Many astronomical calculations involve the use of sines of arcs in a standard circle (a sine is half the chord spanning double the arc) and these may be drawn as lines parallel to one side of the quadrant.

Multiplication may be achieved by the help of scales and the thread and bead. The sine quadrant is well attested in the tenth century and was probably known in ninth-century Baghdad.

The horary quadrant was a quadrant on which “hour-lines” were represented on the face of the instrument by circular arcs issuing from the vertex. The altitude of the Sun is taken by using sights on one side of the instrument and seeing where the thread, weighted with a plumb-bob, falls on the markings. When the position of the bead has been set for the day (e.g., by the noon altitude and the corresponding hour-line), the time can be read off from its position among the hour-lines. In some forms of the instrument a ruler or alidade takes over the functions of the thread and bead. The hours measured by the instrument are “seasonal” hours, for which $1 \text{ h} = 1/12$ time of daylight. The instrument, which is universal, is inaccurate in high latitudes. Underlying the instrument is an approximate formula, which probably came from India, used for calculating tables and also applied to a type of sine quadrant. Horary quadrants and related instruments were often provided with a cursor, or sliding plate carrying markings to facilitate the initial placing of the bead.

There were several further varieties of quadrant – e.g., horary quadrants for fixed latitudes – and also numerous mixed forms. Much of our knowledge of the rarer forms comes from the encyclopedic treatises of al-Marrākushī (thirteenth-century Cairo) and Ibn al-Sarrāj (fourteenth-century Aleppo). The “new” quadrant of Jacob ben Machir (thirteenth-century France), with its combination of horary quadrant and astrolabe projection, appears not to be of Arabic origin.

Quarries in Harappa

Paolo Biagi

Department of Asian and North African Studies,
Ca' Foscari University – Venice, Venezia, Italy

Flint was the most important raw material exploited by the third millennium BCE Bronze Age inhabitants of the Indus Valley and its related territories. Although the importance of this siliceous stone, apart from very few exceptions (Cleland, 1987; Hoffman & Cleland, 1977; Inizan & Lechevallier, 1997; Kenoyer, 1984), has rarely been pointed out even in the most recent publications on the subject (see, for instance, Lahiri, 1992, 2005; Possehl, 2002; Ratnagar, 2004; Wright, 2010), nevertheless, the research carried out mainly during the last 30 years in the Rohri Hills in Upper Sindh (Biagi, 1997), Ongar and the neighboring hills (Biagi, 2005; Biagi & Nisbet, 2011), and Jhimpir (Biagi & Nisbet, 2010; Biagi 2011; Ozcelik, Közem, & Kartal, 2011) in Lower Sindh and also in the artisan workshops of the metropolis of Mohenjo-daro

Quarries in Harappa, Fig. 1 A Harappan flint workshop mainly composed of debitage flakes

(Bondioli, Tosi, & Vidale, 1984; Vidale, 2000; Vidale, Siviero, Sidoti, Guida, & Priori, 2013) has shown the fundamental role played by flint in the wider context of this highly developed urban civilization of the Indian subcontinent.

Although the Rohri Hills have been known since the end of the 1970s as a raw material source (Allchin, 1976), systematic surveys and excavations in the region were undertaken only in the 1990s, after the discovery of impressive clusters of Indus age flint mines in the limestone terraces east of the Shrine of Shadee Shaheed made in 1986 (Biagi & Cremaschi, 1991), by the Ca' Foscari University of Venice (Italy) and the Shah Abdul Latif University, Khairpur (Sindh, Pakistan: Biagi & Starnini, 2011; Biagi & Shaikh 1994; Starnini & Biagi, 2011). The first to report the presence of flint artifacts from this region was Blandford (1880, p. 103), who, in his *Geology of Western Sind*, describing the flat tops of the Rohri Hills south of Rohri, wrote, "The surface of the limestone consists in general of a series of low slopes, corresponding in direction to the dip of the rock. The flints weather out and cover the surface throughout a large area; cores and flakes split from them being scattered about

Fig. 4 The hill to the east of the Shrine of Shadee Shaheed where the first Harappan flint quarries were discovered in 1986

Q

in abundance in some places” (Fig. 1). The same author mentions the recovery of “some flint cores, from which flakes have been chipped, obtained from Lieutenant Twemlow, R. E., in the bed of the Indus. The cores were remarkable for their regularity” (Blandford, 1880, p. 20), although the same author suggested that the cores found in the Indus were manufactured from people different from those who had chipped their tools on the hills around it. These latter cores were first illustrated by Evans (1866

p. 434) who was “superintending excavations connected with a canal, near Shikarpoor, in Upper Scinde.” Furthermore, Blandford (1880, p. 20) reports that “large quantities of flint cores have been found near Sukkur and Rohri, and there is a good collection in the Geological Museum Calcutta” (Figs. 2 and 3).

Apart from the rediscoveries made by Cousens (1929) and De Terra and Paterson (1939), Allchin (1976, p. 477) of the University of Cambridge visited the northernmost edge of the hills, near

Quarries in Harappa, Fig. 5 A concentration of debitage flakes along the edge of a Harappan flint quarry-pit on the Shadee Shaheed Hills

Rohri, in December 1975. Here she noticed “extensive Harappan working floors on the top of several of them,” which were illustrated by the same author in some of her papers (Allchin, 1979, 1999, pp. 291–292), where she describes each of them as “an area large enough for a man to sit cross-legged,” which “had been completely cleared of stones” (Allchin, Goudie, & Hedge, 1978, p. 276).

Before the complete destruction of this important archaeological area, due to industrial quarrying (Biagi, 2007), I visited the limestone mesas south of Sukkur in April 1985 and again in January 1986, when groups of large flint mines were discovered by me and Professor M. Cremaschi of Milan University in the Shadee Shaheed terraces (Figs. 4, 5, and 6).

The Rohri Hills

The Rohri Hills, which are some 40 km long and 16 wide, extend in a north–south direction between the course of the Indus and the cities of Sukkur and Rohri, in the north, and the westernmost fringes of the Thar Desert, in the south (Fig. 7), which, in this part of the country, is

Quarries in Harappa, Fig. 6 The circular appearance of a flint quarry-pit at Shadee Shaheed

**Quarries in Harappa,**

Fig. 8 A salt-lake basin near the caravan city of Thari, south of the Rohri Hills

Q

very rich in salt-lake basins (Figs. 8 and 9). The hills consist of fossiliferous limestone rocks of the Brahui formation attributed to the Middle Eocene/Early Oligocene period, very rich in seams of good quality flint (Blandford, 1880, p. 103), which attracted the prehistoric populations at least from the Early Paleolithic Acheulian period onwards (Biagi & Cremaschi, 1988; Biagi, Kazi, & Negrino, 1996; Biagi, 2008; Fig. 10). They separate two very different

environmental regions, the Indus Valley to the west and the Thar Desert to the east. Their eastern fringes are lapped by the Nara Canal, which flows inside the old bed of the Hakra–Ghaggar River. The hills are limestone mesas (Fig. 11), dissected by erosion and deeply incised by old river courses (Fig. 12).

As mentioned above, the surveys carried out in 1986 led to the discovery of groups of Indus flint mines and workshops in the Shadee Shaheed area

Quarries in Harappa,

Fig. 9 The high sand dunes surrounding the salt-lake basin of Sāin Sim

Quarries in Harappa, Fig. 10 Acheulian bifaces on the surface of a workshop near the tomb of Ziarāt Pir Shabān on the Rohri Hills

of the hills (Biagi & Cremaschi, 1991). Here, the most impressive structures were located along the edges of the limestone plateau (Fig. 13). From the surface the mines consisted of almost circular empty areas, representing the mine pits, filled with aeolian sand, blown from the Thar Desert dunes, and heaps of limestone block, deriving from prehistoric mining activity (Fig. 14). All around these structures, flint workshops were noticed (Fig. 15), represented by scatters of flint flakes and blades among which were typical Indus-elongated blade cores and characteristic bullet cores with very narrow bladelet detachments (Fig. 16). During the same survey,

it was possible to observe that large areas of this part of the hills had already been highly damaged by illegal activities carried out by limestone quarriers (Figs. 17 and 18) and that even wider devastations were in progress by modern industrial limestone quarrying (Fig. 19). Nevertheless, it was possible to notice that the area covered by the presence of groups of prehistoric mines was very wide and extended all over the central–western region of the hills. Indus Civilization mines were discovered also in the valleys of the internal mesas (Fig. 20).

The Excavation of Mine RH862

The excavation of mine RH862 was carried out between 1995 and 1998 (Starnini & Biagi, 2011). This mine lies along the western edge of the Shadee Shaheed Hills, some 3.5-km south of the shrine that bears the same name (Fig. 21). “The site is part of an impressive, wide ring-shaped group of features, some 120 m in diameter, related to a Harappan flint mining activity area” (Starnini & Biagi, 2005, p. 1). The mine was surrounded by several flint scatters and workshops (Negrino, Ottomano, Starnini, & Veesar, 1996), one of which was connected with the production of narrow bladelets from typical bullet cores (see Fig. 16). As mentioned above,

Quarries in Harappa,

Fig. 11 The western fringes of the central part of the Rohri Hills

Quarries in Harappa, Fig. 12 An aerial view of the Rohri Hills at Shadee Shaheed and their very corrugated system

the excavation was carried out during four fieldwork seasons. It was aimed at understanding the mining techniques employed by the Indus Civilization workers and the understanding of its chronological attribution. Thanks to the discovery of two small pieces of *Zyzyphus* cf. *nummularia* charcoal it was possible to obtain an AMS radiocarbon date of the excavated pit. It gave the result of $3,870 \pm 70$ uncal BP (GrA-3235), which attributes the structure to the mature Indus Civilization (Biagi, 1995). The excavation covered an area of some 60 m^2 down to a depth of 1.5 m, where the floor reached by the Indus workers was found (Fig. 22), inside which dozens

Quarries in Harappa, Fig. 13 Professor Cremaschi positioning the first Harappan flint quarries at Shadee Shaheed in January 1986

of extractive holes containing flint nodules still in situ (Figs. 23 and 24) were discovered (Starnini & Biagi, 2005, Fig. 4). The excavation did not yield any metal or other extractive tool which might have been employed for breaking the fissured limestone and reaching the flint seam. In contrast, it produced a huge amount of flint debitage

Quarries in Harappa, Fig. 14 Aerial view of part of the main system of Harappan, flint quarry-pits on the hills near Shadee Shaheed

(Fig. 25) and several hammerstones and cores from the same material. On the basis of the field observations, “the preparation of the precore rough-outs was most probably performed inside the quarry trench, or along its edge, as many decorticating flakes, pre-forms and typical crested blade-like-flakes found inside the ditch fill should indicate” (Starnini & Biagi, 2005, p. 5).

The Ongar, Daphro, and Bekhain Hills

The surveys carried out on the Ongar, Daphro, and Bekhain Hills, south of Hyderabad, some 8 kms north of Jhikar, in Lower Sindh, led to the discovery of other flint-extractive mines also in this region (Biagi, 2005; Biagi & Franco, 2008; Biagi & Starnini, 2008). Indus flint extraction trenches were discovered mainly along the edges of a narrow hill still intact that elongates between Ongar and Daphro. Also a few points of Daphro Hill revealed the presence of flint-extractive systems similar to those observed along the western mesas of the Rohri Hills in Upper Sindh (Figs. 26 and 27). Apart from

Quarries in Harappa, Fig. 15 Very wide, circular concentration of Harappan debitage flakes near Shadee Shaheed

Quarries in Harappa, Fig. 16 Harappan bullet cores with very narrow bladelet detachments

Quarries in Harappa, Fig. 17 Large area cleaned by the quarries. The modern heaps of flints are clearly visible

Quarries in Harappa, Fig. 18 Modern handmade quarrying along the fringes of the Rohri Hills mesas

ditches excavated along the edges of the limestone mesas, the surveys revealed the systematic recurrence of flint workshops (Fig. 28), undoubtedly attributable to the Indus Civilization, as indicated by the presence of characteristic elongate, subconical, flint cores with long blade detachments (Fig. 29). A similar situation has been noticed also along the sides of Bekhain, a low hill, located just to the south of the abovementioned two, where most of the Indus flint mines had already been destroyed at the time of their discovery. At Bekhain Hill, the occurrence of large-sized pre-cores (Fig. 30), already prepared for being transported, is of major interest. Single pre-core specimens have been found also at Mohenjo-daro, the Rohri Hills, and Kahi Bhandari near Badin (Khan, 1981), close to the Rann of Kutch. This discovery is particularly important because it indicated that not only the final products, such as well-defined types of blades and bladelets, were transported to the major centers of the Indus Civilization for being transformed into instruments for craft production around the middle of the third millennium BCE, but also complete, large blocks of flint already prepared for their transport. It is highly regrettable that most of the above important third millennium BCE extractive areas were

Quarries in Harappa,

Fig. 19 Machine quarrying in the central part of the Rohri Hills as it was in 1999

Quarries in Harappa,

Fig. 20 An internal region of the central part of the Rohri Hills rich in groups of Harappan flint quarries and workshops

devastated during the last 50 years by illegal limestone quarrying and that they are also “exploited to produce flint cores and blades, seemingly to decorate private residence walls” by a Karachi enterprise (Biagi & Nisbet, 2011) without any interest by both local- and national-appointed authorities.

Jhimpir

The presence of a flint source in the Ranikot bed northwest of Jhimpir railway station had already

been reported by Blandford (1880, p. 153). Although a survey conducted in the area in 2010 did not reveal any important flint seams in situ in the limestone deposits, further investigation conducted south of the above small town led to the discovery of two distinct flint outcrops in two limestone terraces oriented in an east–west direction (Biagi 2011; Biagi & Nisbet, 2010). Further investigations in the area undertaken the following year showed that the same flint seam, although interrupted, continues further to the west, following the same direction. The most evident traces of prehistoric exploitation were

Quarries in Harappa, Fig. 21 The beginning of the excavation of the Harappan flint quarry-pit 862 in the Rohri Hills

Quarries in Harappa, Fig. 26 A large, Harappan flint workshop discovered in the Daphro Hill in 2006

Quarries in Harappa, Fig. 27 Three parallel, Harappan flint extraction trenches opened along the edge of the Daphro Hill

recorded on a flat terrace that elongates close to the Larinadi riverbed. Here, the westernmost part of the mesa is marked with extraction trenches surrounded by workshops marked by the presence of blade cores, debitage flakes, crested blades, and bifacial picks made from the same flint. Good-quality flint seams were observed also at the top of an inclined terrace located about one mile south of the abovementioned one. At present, this seam is exploited on a small scale for industrial purposes.

Considerations

The discoveries made in the Rohri, Ongar, Daphro, and Bekhain Hills and Jhimpir have demonstrated that flint was still extremely important during the flourishing of the third millennium BCE Indus Civilization. Flint was extracted not only from the Rohri Hills quarries but also from other mining areas which were unknown to archaeologists until a few years ago and most probably also from other outcrops still to be discovered (Biagi, 2010, p. 13). During this period, they were traded over long distances at least as far as Harappa, to the north (Law, Baqri, Mahmood, & Khan, 2002–2003), and the Indus cities located along the north Arabian Sea coast, to the south

Quarries in Harappa,

Fig. 28 A long Harappan flint extraction trench excavated along the edge of the Daphro Hill

Quarries in Harappa, Fig. 29 Harappan elongated core for the production of long, narrow flint blades with parallel edges

Quarries in Harappa, Fig. 30 Harappan flint pre-core already oval-shaped for its exportation to one of the Harappan urban centers of the Indus Valley

(Gadekar, Ajithprasad, & Madella, 2013). The complicated extractive system, which undoubtedly involved a great number of workers and knappers (flint shapers), and the extraordinary great number of mines discovered on the Rohri Hills indicate that this was undoubtedly a main extractive center and that flint was of primary importance at least during the mid-third millennium BCE mature Indus Civilization. Although the extraction systems have not been fully understood and the trade routes are still poorly known,

there is no doubt that the role played by this raw material has so far been underestimated by archaeologists.

Furthermore, as already remarked on many occasions, the damage to a more comprehensive knowledge of the Indus Civilization caused by the systematic devastation, for illegal industrial activities, of most of the aforementioned archaeological areas of Upper and Lower Sindh is remarkable (Dar, 1991; Allchin, 1999, p. 298; Biagi, 2007).

³Faculte des Sciences de Gabes, GS, Tunisia

Since antiquity, stones have played an important role in Mediterranean civilizations. Thanks to the surveys and the studies of both geologists and archaeologists, the extraction quarries are partly identified. Tunisian quarries are numerous, and since the Punic period they have provided several types of sandstone and limestone of good quality for construction. The stone extraction techniques employed by the quarry workers have undergone great changes from antiquity to the present.

This present study deals with the geological features of the cut stones, a view of the location of most of the Tunisian quarries, and finally the stone extraction techniques which have been used since ancient times.

Geological Features of Tunisian Stones

Tunisia has many useful mineral resources, particularly in phosphates, clays, extra-siliceous sands, charge substances, raw materials for mineral binders (gypsum, limestone, calcareous clay, etc.), and stones. These last have been exploited for more than 2000 years because of their good mineralogical, physical, and chemical features. Indeed, these stones reveal a good structural resistance mainly linked to their mineralogical composition; they have calcites, dolomites, and sometimes a very low proportion of quartz. Their long use, from the Libyc dynasty to now, is real proof of their strength. Furthermore, the presence of these stones in wide-scale geological areas situated not far from urban centers both with

their attractive appearance (color, texture, and homogeneity) encouraged the quarriers to exploit them for different uses.

Tunisian stones, with their great variety of colors ranging from light to dark, allowed them to meet all the architects' and town planners' requirements from all over the world (Fig. 1).

The Tunisia geological map shows sedimentary outcrops ranging from the Upper Permian age to the Quaternary except for a few sporadic outcrops made of metamorphic and magmatic rocks, most of them situated in the far northwest of the country (Fig. 2).

These stones belong to six geological periods characterized by completely different sedimentology and paleogeographic conditions: Jurassic, Cretaceous, Eocene, Miocene, Pliocene, and Quaternary.

Jurassic

The stones that come from this period are:

- Gray and black dolomites and dolomitic limestone veined by white calcite. They are found in the Jurassic massifs of the Tunisian ridge.
- Yellow, orange, red, green, and gray low metamorphosed dolomites in Jebel Chemtou and Jebel Ichkeul (northern Tunisia).
- Beige and punctuated with red in the region of Ghomrassen where the thick dolomitic limestone bar stands as a landmark all over southern Tunisia.

Cretaceous

This period produced stones with the following features:

- Black limestone with occasional red veins filled with oxide of iron from Albian-Aptian outcrops. These stones are present in the regions of Boulahneche (Governorate of Kasserine) and of Bou Arada (Governorate of Siliana).
- Yellow, beige to grayish carbonated rocks of the so-called bar of Gattar from Turonian age. These types of stones outcrop mainly in the south of Tunisia and particularly in the regions of Gabes and Matmata.

- Reddish and whitish biolithite calcareous from Cenomanian age which are present in Jebel Keddel (around 20 km south of Tunis).
- Beige, gray, and reddish calcareous (Thala type) from Abiod formation of Campanian-Maastrichtian central Tunisia and more particularly in the region of Thala (Governorate of Kasserine in center-eastern Tunisia).

Eocene

When it is a nummulitic facies, the Lower Eocene is used as varicolored marble stones such as the Kesra type. Indeed, the colors are the most varied: black, gray, beige, yellow, red, and whitish.

Miocene

Yellowish bioclastic sandy limestone with lamellibranchs has been identified especially in the region of Mahdia.

Pliocene

The Pliocene stones consist of bioclastic sandy limestone which have revealed very good physical and chemical features. They are essentially located in the region of Monastir and Nabeul.

Quaternary

Tyrrhenian Dune Line

The Tyrrhenian dune line, ranging from a few meters to a few kilometers wide, outcrops all along the Tunisian coastline and provides carbonated sandstones, most often bioclastic (lamellibranchs, gasteropoda, and strombes).

The Holocene Dune Line

This dune line is an ancient beach constituted of lamellibranch sandstones whose color ranges from red to yellowish. They are found at El Haouaria in the Governorate of Nabeul.

Location of the Quarries

According to current data, Tunisian quarries have been known since the Punic period. They are situated essentially in the sedimentary outcrop belonging to six different geological periods in

Quarries in Tunisia, Fig. 1 Colored range of Tunisian stones (Mohamed Essghair Gaied). 1, pink of Chemtou; 2, yellow of Chemtou; 3, gray of Chemtou; 4, green shale of Hairech; 5, Aziza black; 6, Aziza Berber; 7, Aziza brown; 8, Ghomrassen type; 9, 10, 11, 12, and 13, limestone reef (type Keddel); 14, 15, and 16, Boulahneche type or black Thala; 17, Matmata type; 18 and 19, Thala imperial; 20,

Thala royal; 21, Thala gray; 22, Thala veined or fissural; 23, Thala flowery or shelly; 24, Thala pink or Gabes stone; 25, Kesra black; 26, Kesra gray; 27, 28, and 29, Kesra beige; 30, Kesra gray-beige; 31, Kesra red or pinkish stone Mateur; 32 and 33, Kesra beige or Dahmani stone; 34, Foussana stone; 35, El Hamma or Gabes stone; 36, Chebika or Kairouan stone

Quarries in Tunisia, Fig. 2 Geological map of Tunisia (Mohamed Essghair Gaied), (ETAPE, 2010)

northern, central, and southern Tunisia. This type of outcrop has most often provided a good quality building stone.

In northern Tunisia, two quarry areas can be distinguished: the coastal quarries and the inland ones. The first ones are mainly located in the regions of Cap Bon (Holocene sandstones), Bizerte (Tyrrhenian or Würmian sandstones, Jurassic dolomitic limestone), and Tabarka (Eutyrrhenian sandstones, Eocene limestone) (Fig. 3). Concerning the inland quarries, they have been found in the regions of Beja (Eocene limestone), Jendouba (Eocene limestone, Jurassic dolomitic limestone), Kef (Eocene limestone), and Zaghuan (Jurassic limestone and travertine) (Fig. 3).

In central Tunisia, the quarries are found both in the Sahil region (Pliocene and Miocene sandstone-limestone, Tyrrhenian carbonated sandstones, Holocene biolithite sandstones) and inland in the regions of Thala, Siliana, Kasserine, and Kairouan (Eocene limestone) (Fig. 3).

In southern Tunisia the quarries identified are less numerous and less preserved than those in northern and central Tunisia. They have been found in the regions of Gabes (Cretaceous recrystallized limestone, Tyrrhenian sandstones), Tataouine (Trias dolomitic limestone, travertine), and Djerba (Tyrrhenian shelled limestone) (Fig. 3).

Extraction Techniques

It is mainly thanks to archaeological evidence that the quarrying techniques are well known nowadays. Indeed, the best-preserved quarries from sandstone and limestone rocks provide precious information concerning the different exploitation techniques used by the quarriers from antiquity to now.

Ancient Extraction Techniques

Two types of exploitation have been identified: open-air exploitation and in galleries.

In open-air exploitation, the quarry worker starts to choose the good quality rock for

construction by taking off the sand and the vegetation layer which cover this rock. Then, following the natural planes of weakness in the bedrock (joints, stratigraphic levels), he outlines the block to be cut by making slits in the three non-detached sides with a pick or *escoude*. Afterwards, he widens and deepens these slits using different tools such as pick, *escoude* and/or sledgehammer, awl, and chisels in order to get extraction trenches wide enough for the tool to be easily moved in. The length and the width of these extraction trenches correspond to the size (or volume) of the block to be cut (Fig. 4).

The sizes (length $\times$ width $\times$ thickness) of the well-preserved extraction trenches on the quarry faces range from $0.25\text{--}2.50 \times 0.08$ to $0.15 \times 0.15\text{--}0.75$ m. Finally, in order to extract the block, the quarry worker makes a line of rupture at the lower forward side where holes are made to insert metallic wedges on which two or three quarriers hammer. When this last step is not successfully done, the lower part of the block remains attached to the rock.

The coastal quarries are often separated from the sea by a non-detached straight line of the rock in order to prevent water from entering which would interrupt all activities. The extracted blocks give to the quarry faces either a beveled edge or stepped profile. When the thickness of the pumice stone upper layer becomes of poor quality for building, the quarry worker gives up open-air exploitation and opens up a gallery. The underground quarries known under the name of *ghar* consist of at least one room and one or two entrances situated to the eastern or western sides providing the rooms with daylight and fresh air.

The technique of block extraction in galleries is the same as in the open-air quarries. Yet, inside the gallery, in order to strengthen the ceiling of the quarry, a kind of natural pillar is cut into the rock which is not the case in the open-air quarries (Fig. 5). Most of the rooms in the underground quarries are medium and small sized, so they are rather well ventilated and lit during the day. In the scarce large-sized ones which are poorly lit since they have not got lighting shafts, the quarry workers have to light the far end of the gallery with oil lamps.

Quarries in Tunisia, Fig. 3 Location map of the identified quarries (Ameur Younès)

Quarries in Tunisia, Fig. 4 Extraction trenches in Simitthus Roman quarry (Ameur Younès)

Quarries in Tunisia, Fig. 6 Modern extraction techniques of sandstone blocks in Rejiche quarry (Ameur Younès)

Quarries in Tunisia, Fig. 5 Natural pillar in the underground Roman quarry in Ksour Essaf (Ameur Younès)

The cutting marks left on the gallery faces give them a beveled edge profile. The extracted blocks are small and medium sized, but with an occurrence of the small ones. These small-sized blocks are easier to move in the galleries than the medium- and large-sized ones.

Though the extraction technique in the galleries has not changed since ancient times, the open-air exploitation has undergone great changes.

Modern Extraction Technique

The ancient open-air extraction technique was used until the second half of the twentieth century. Then, the mechanization of the quarry

exploitation changed from the ancient extraction techniques. Today, the quarry men follow two different techniques according to the type of the rock to be extracted.

For sandstone rocks, the quarry men take off the upper layer of the soil, and then a driver operates a disk saw machine to cut uniform square sandstone blocks (Fig. 6). These blocks are then picked up and loaded into trucks to be transported to building sites.

For extracting marble limestone, the quarry men take off the sand and vegetation layer covering the limestone banks to be extracted, and then they outline the blocks to be cut following the natural planes of weakness in the bedrock. Afterwards, using a diamond thread saw machine, the technical driver cuts up large-sized marble limestone blocks which are finally carried and transported from the quarries into marble stone factories where they are cut, polished, and sculpted (Fig. 7).

Conclusion

Geologists and archaeologists have located most of the Tunisian stone quarries. These quarries have provided several types of good quality stones for construction thanks to their different geological formations. Exploitation techniques

Quarries in Tunisia, Fig. 7 Modern extraction techniques of marble limestone blocks in Chemtou quarry (Ameur Younès)

have remained the same since the Punic period until the second half of the twentieth century when the quarry men began to use machines in order to cut stones in the open-air quarries. Both the ancient and modern extraction techniques of blocks in Tunisia are similar to the exploitation techniques identified in the quarries situated in the Mediterranean countries. Yet, because of scarce documents available on the administration of many quarries, it is not possible to know exactly how they were administered.

Quinoa. A Millenary Grain in Northern Argentina

María del Pilar Babot and Salomón Hocsman
Archaeological Institute and Museum, Natural Sciences Faculty and Miguel Lillo Institute,
National University of Tucumán, San Miguel de Tucumán, Tucumán, Argentina

Quinoa (*Chenopodium quinoa*) is a plant of South American origin able to flourish in poor soils and conditions often regarded as marginal for other crops. Its panicles contain a large number of grains basically composed of starch and rich in protein, mineral nutrients, and oils (Ayala, 2004; Repo-Carrasco, Espinoza, & Jacobsen, 2003).

Since the first information collected by Armando Hunziker between the 1940s and 1970s, the background for pre-Hispanic cultivation and use of the quinoa in what is today Argentina has been considerably enlarged. The renewed interest in this plant in the last decade

Quinoa. A Millenary Grain in Northern Argentina, Fig. 1

West side of Argentina. From west to east in the Northwest region there are the High Puna, mesothermal valleys, mountainous rainforest, mountainous Chaco forest, and Chaco plain

has drawn a more precise, though still fragmented, panorama of the millenary use of this South American grain. Even though the southern Andes has been traditionally considered marginal regarding agricultural development in the Central Andes, the new discoveries indicate that, quite to the contrary, a long tradition exists in the local use of this plant.

Numerous seeds and fragments of both panicles and stalks, as well as microscopic remains of this plant on ancient tools, are widely distributed in the western part of Argentina, from the northern locations in Jujuy province to the Cuyo area

in Mendoza province to the south (Fig. 1). These findings resulted from the careful implementation of field and laboratory archaeobotanical techniques focused on the recovery of ancient botanical material from site sediments (Fig. 2) as well as from the objects yielding microscopic residues of plant manipulation.

In the Northern region, available information indicates the use of quinoa by the societies inhabiting several archaeological sites in the Puna but also in the hillsides and valleys of arid or semiarid climates, the mountainous rainforests, and the Chaco environments nearby,

Quinoa. A Millenary Grain in Northern Argentina, Fig. 2 Dry sieving is an archaeobotanical technique to separate sediment fractions that contain archaeological plant material, according to the size of a series of sieve meshes. Sediment fractions obtained are scanned under a magnifying glass, and plant material is picked up with a pin. (a) Sieved sediment fraction, from 1 to 1.99 mm, under the magnifying glass. (b) Detail of different color quinoa seeds, before being picked up from the sediment

far before the arrival of the Inca and European populations. Historical chronicles as well as travelers' tales give hints about its cultivation even in later Colonial and Republican times.

A number of references for the use of quinoa were recovered at some archaeological sites in the Punilla river basin (Puna of Catamarca), a high-elevation desert environment some 3,500 masl. The earliest date for quinoa manipulation corresponds to hunter-gatherer groups who occupied the area some 4,500 years ago. These societies seem to have been responsible for the

beginning of camelid husbandry practices and their eventual evolution into llamas (Aschero, Izeta, & Hocsmán, 2014). It may be possible that, at the same time, they would have engaged in small-scale experimental cultivation of some plants to collaborate with the food provision to the familiar unit. Both activities would be complemented by hunting, plant gathering, and exchange of some products with other areas. Thanks to these mechanisms, even in those early times, the societies inhabiting the whole Argentinian Puna manipulated a wide spectrum of plants and animals for food, crafting, habitat accommodation, illness treatment, and ritual practices (Babot, 2011; Fernández Distel, 1986).

Many of the plants used, particularly the ones intended for food, did not survive in the archaeological sites of early dates. Nevertheless, they are known by microscopic remains called microfossils, which are preserved on the surface of grinding stones and projectile points/knives of the Quebrada Seca 3 site (Antofagasta de la Sierra, Catamarca), for instance (Fig. 3). These microfossils are testimony to the preparation previous to the consumption of several tubers and roots, cactus fruits (*Opuntia* sp.), wild grass seeds, maize grains (*Zea mays*), and pseudocereals such as quinoa and *kañiwa* (*Chenopodium pallidicaule*, a plant of the same genus as quinoa) (Babot, 2011; Babot et al., 2013). Some of the plants manipulated at the time, like maize and Cactaceae, would have originated in warmer and more humid ecological zones than the Puna. However, species prone to Puna climate, such as quinoa, may have been locally produced and harvested. This idea is supported by the evidence of manipulation of a seed similar to quinoa by Puna societies, who used to know and consume wild amaranth grains (*Amaranthus hybridus*) some 8,000 years ago (Arreguez, Martínez, & Ponessa, 2013).

The next milestone in the history of quinoa use in the Punilla river basin may be placed about 3,500 years ago. This is the date for the earliest quinoa stalks remains found so far. It is estimated that, at that date, the small agricultural fields and the spaces for postharvest activities

Quinoa. A Millenary Grain in Northern Argentina, Fig. 3 (a) View of Quebrada Seca Gorge at 4,000 masl in the Punilla river basin (Southern Puna of Argentina). (b) Handstone from Quebrada Seca 3 site – the scale bar is in centimeters. (c) Drawing showing the way of using a

handstone on a lower grinding tool. (d) Microscopic starch grain of *Chenopodium* cf. *quinoa* (approximately 20 μ m length) recovered from a handstone from Quebrada Seca 3 site (4,500 years old)

would be nearby the residential areas, where the different parts of the plant were consumed. One of these residential sites is the Peñas Chicas 1.3 rock shelter in the Las Pitas middle river basin (Antofagasta de la Sierra, Catamarca) (Hocsman, 2006; Fig. 4). This place yielded a fragment of stalk morphologically related to a quinoa with ancient features (Aguirre, 2007), testifying to the harvesting of the plant. A few meters from this site, the Peñas Chicas 1.1 rock shelter, of a similar chronology, provided microscopic starch grains corresponding to the remains of quinoa ground into flour (Babot, 2011). Local populations would have incorporated other plants into their food repertoire, such as *oca* (*Oxalis* cf. *tuberosa*), common potato (*Solanum* cf. *tuberosum*), edible canna (*Canna* cf. *edulis*), algarrobo (*Prosopis* spp.),

and wild native walnut (*Juglans australis*) (Babot, 2011).

The distance between spaces for quinoa cultivation and their related residential sites seem to have remained unaltered throughout time at least until 1,400 years ago, as indicated by the desiccated remains of stalks and panicles recovered in residential sites of different chronologies: Cueva Salamanca 1, El Aprendiz, and Punta de la Peña 9 (Arias, Aguirre, Luque, & Escola, 2014; Babot, Aguirre, & Hocsman, 2013; Pintar, 2014). Then, when agricultural intensification increased toward 1,000 years BP in several locations in the Punilla river basin (Olivera & Tchilinguirian, 2000; Salminci, Tchilinguirian, & Lane, 2014; Tchilinguirian & Olivera, 2000), quinoa was still being locally produced as is proved by quinoa seeds and panicle fragments at Punta de la

Quinoa. A Millenary Grain in Northern Argentina, Fig. 4 (a) View of gorges at 3,600 masl in the middle basin of Las Pitas River (Southern Puna of Argentina).

In the *center* of the image, there is the archaeological area of Peñas Chicas. (b) Pestle from Peñas Chicas 1.1 site (3,500 years old)

Peña 4 and Punta de la Peña E sites until 600 years before now (Rodríguez, Rúgolo de Agrasar, & Aschero, 2006; S.M.L. López Campený, personal communication, November 22, 2013). Such findings, spread throughout time, indicate the presence of a local and uninterrupted tradition of quinoa cultivation covering three and a half millennia in the southern Argentinian Puna.

The agricultural instruments used to manipulate quinoa are still unknown for the early moments of its cultivation before 2,000 years BP. However, between 1,700 and 1,200 years BP, herding and horticultural societies are known to have used large lithic objects with cutting edges related to modern knives or sickles for these tasks, to the point of making them blunt (Escola, Hocsman, & Babot, 2013; Fig. 5). These pieces were recovered in different sites in the Punilla river basin (Punta de la Peña 9, Punta de la Peña 12, and Casa Chávez Montículos 1). Knives would have been useful in the many activities implied in the agricultural cycle, including thinning or desuckering the green plant and reaping the mature panicles of the different pseudocereals. Consequently, their cutting edges have preserved microscopic residues of quinoa, *kañiwa*, and some amaranth plants such as *kiwicha* or *chaclión* (*Amaranthus caudatus* and *Amaranthus mantegazzianus*). Cultigens are known to have been attacked by pests as well,

as tiny moth scales were identified among the remains. Some of these ancient instruments were recovered from storage places, carefully arranged, in both residential and de-kernel and threshing areas. Additionally, knives were found close to spaces which may have been devoted to the highland cultivation of quinoa, particularly next to river margins where water was available for irrigation. Currently, it is cultivated in small orchards with a large diversity of floral examples, where edible plants alternate with ornamental and medicinal species (Fig. 6).

Both the knives and the severed stalks found in Antofagasta de la Sierra cover a wide chronological range and suggest a common tradition of harvesting the pseudocereal by cutting the stalk instead of uprooting the complete plant.

Similar lithic knives were also located in many valley sites in Catamarca province beyond the Puna region: El Bolsón, La Ciénega, Hualfín, El Cajón, and Yocavil (Escola, Hocsman, & Babot, 2013). Microfossil studies on the materials from El Bolsón documented that the knives were used with a similar purpose to the ones recorded in the high Puna (Maloberti & Mauri, 2013).

The process followed by quinoa seeds after harvest can be tracked from the findings in ancient kitchens, rubbish middens, or small deposits of plants and vessels in caches inside several archaeological sites in the Punilla river basin such as Cueva Cacao 1 or the locations

of Argentina). (b) Local varieties of quinoa in the Morales Family's high-altitude orchard at Las Pitas River

aforementioned (Babot, Aguirre, & Hocsmán, 2013; Olivera, 2006; Fig. 7). Archaeological seeds are somewhat more recent than stalk remains, dating to 3,000 or 2,500 BP, but they were present until Colonial times. Grains are occasionally recovered together with the terminal

fragments of panicles, constituting the earliest record of the postharvest quinoa treatment stage (Fig. 8). Similar to modern times, dry panicles would have been de-kerned by carefully patting and rubbing. After that, the detached material would have been threshed and winnowed to

Quinoa. A Millenary Grain in Northern Argentina, Fig. 7 Archaeological quinoa seeds from the Punilla River Basin (Southern Puna of Argentina). separate the grain from the remaining tiny residues. The recovery of the waste from these activities in some archaeological sites such as Punta de la Peña 9 indicates that the stages of detachment and dusting were carried out near residential places. At least a threshing enclosure, with a mortar-and-slab floor and simple *pirca* walls resembling pre-Columbian and modern so-called *kayanas* in the Bolivian Altiplano, was recorded in this archaeological site (Escola, Hocsman, & Babot, 2013).

Beyond the northern area of Catamarca, Puna records of quinoa are less frequent, but they may increase with the advance of research in progress. Available evidence indicates that in the Puna highlands of Salta and Jujuy provinces, this Andean grain was among the first plants cultivated by local societies, as also happens in Antofagasta de la Sierra. Coat removal and grounding of quinoa seeds were included in the daily activities carried out in the residential areas of the

Quinoa. A Millenary Grain in Northern Argentina, Fig. 8 Endings of the quinoa panicles, from Punta de la Peña 9 site (1,500 years old) in the Punilla River basin (Southern Puna of Argentina). They are waste from the quinoa cleaning – the scale bar is in centimeters

early agricultural and herding human groups living in El Aguilar area (Puna of Jujuy), as evidenced in the microfossil plant remains found on grinding stones dated between 3,000 and 2,600 years ago (Babot, Hocsman, Piccón Figueroa, & Haros, 2012). The grain was incorporated into several culinary recipes whose ingredients accumulated on some ceramic sherds from the Cueva de Cristóbal archaeological site (Babot, Hocsman, Piccón Figueroa, & Haros, 2012), one of the earliest pottery records in the southern corner of South America. In the case of El Aguilar, the use of quinoa was documented as a living practice even in Spanish Colonial times some 400 years ago, exemplified by the seeds found in Cueva El Portillo rock shelter.

Some seeds morphologically similar to quinoa were located in the Puna of Salta. Due to charring, their identification has to be restricted to the genus *Chenopodium*. The seeds were recovered in a garbage midden at the agropastoral village of Matancillas 2 (San Antonio de los Cobres), dated toward the beginning of the era (Muscio, 2004). Not far from this site, in the northern head of the Calchaquí Valleys, which provides a natural access to the Puna, Dr. Verónica Lema also recorded quinoa with a chronology approximately 450 years earlier than the former site, in the Puente del Diablo Cave (La Poma) (V.S. Lema, personal communication, November 22, 2013).

So far, the southernmost finding of ancient quinoa in the Puna region as well as in all of northwestern Argentina took place in Tinogasta, Catamarca province. In this case, quinoa seeds were part of the grave goods of an adult male who died some 600 years ago (Ratto, Lema, & López, 2014).

Going down the eastern border of the Puna, between 3,500 and 2,400 masl, the landscape presents numerous valleys and hillsides. Due to natural conditions, which are usually adverse for the preservation of organic materials, these environments are poorer in archaeobotanical findings than the Puna desert. However, some sites characterized by peculiar conditions have provided valuable information about the ancient use of quinoa and other plant resources, shedding light on the trajectory of this grain in the lowlands for the last two millennia, simultaneously with its production and consumption in the Puna.

In the valleys, the outstanding recovery of *Chenopodium* seeds morphologically similar to quinoa in the village of Cardonal (El Cajón Valley, Catamarca province) is unique in the area due to their early chronology, dating back to the first centuries of the era. Quinoa was one of the useful plants villagers manipulated in their ancient kitchens, among which maize, potatoes, and common beans should be also mentioned (Calo, Bugliani, & Scattolin, 2012). Toward the east, the Pampa Grande contexts in Las Pirguas Hills (Salta province) are testimony to other exploitations of this grain, represented here in mortuary rites (Hunziker, 1943). This custom is indicated by the presence of quinoa seeds in a vessel, together with other plants accompanying human burials dated to 1,200 AP. Hunziker's was one of the pioneer case studies of archaeological quinoa in the country, developed as early as the 1940s in collaboration with Francisco de Aparicio. As much as quinoa, *kiwicha* and other wild *Chenopodium* and *Amaranthus* grains were identified (Hunziker, 1943). Once in the mountainous rainforests of northwestern Argentina, Las Pirguas is the westernmost enclave where archaeoquinuas were found.

Toward the last centuries before the arrival of the Inca to the territories in Northern Argentina,

the quinoa "trace" seems more defined in the archaeological sites of the temperate valleys, which in turn presents different environmental conditions. In the pre-Puna locations in the El Bolsón Valley (Catamarca province), two cases may be mentioned, both of them dated to some 1,000 years before today: Cueva de las Máscaras and Alero Los Viscos, two nearby shelters in the Los Viscos Gorge (Korstanje, 2007). The latter yielded quinoa and amaranth seeds in a garbage midden located inside the residential place.

At a lower altitude and near the border with the eastern mountainous rainforests, Cueva de Los Corrales Cave site, in the Tafi Valley (Tucumán province), constitutes another hillside location where quinoa, *kiwicha*, wild *Chenopodiaceae*, and wild *Amaranthaceae* seeds were discovered in a full-use context, as part of a larger repertoire of native plants (Arreguez, Martínez, Oliszewski, & Ponessa, 2015; Fig. 9). To the north, on the border between Argentina and Bolivia, the Río Grande de San Juan basin is also informative regarding quinoa consumption and the disposal of charred grains in the garbage middens of the Finispatriae site (Nielsen, Angiorama, Maryaňsky, López, & Ávila, 2013). All these hillside sites as well as the large urban conglomerates in the Calchaquí Valleys (Salta), where this Andean grain was abundant, suggest that quinoa must have been a key resource for the native societies in the valleys of northwestern Argentina between the centuries after 1,000 years BP and the Inca arrival.

The situation does not seem to have changed under Inca control. The finding of numerous charred grains similar to quinoa and their wide distribution in the valley (Puerta de La Paya, Cortaderas Bajo, Valdez, and Potrero de Payogasta sites in Salta province) suggest that the regional production and use of the grain were not interrupted and that the different social groups living in the area had access to this plant (Lennstrom, 1992).

Summing up, the remains of seeds, stalks, and panicles and microscopic remains of quinoa plants cover a wide geographical range in northwestern Argentina: from the current political border with Bolivia in the Río Grande de San Juan

Quinoa. A Millenary Grain in Northern Argentina, Fig. 9 (a) Los Corrales Gorge in the mesothermal valleys area of Northwest Argentina. (b) Lower grinding tool from Cueva de los Corrales 1 site that contained microscopic remains of grinded pseudocereal seeds – the scale bar is in centimeters

river basin to the north to Tinogasta, in Catamarca, to the south and from Antofagasta de la Sierra, near the border with Chile to the west, to Pampa Grande, Tafí Valley, and the Chaco area near the eastern mountainous rainforest in Jujuy to the east. Besides this region, the Sierras de Córdoba area, at the center of the country, also reported the pre-Hispanic cultivation of this Andean grain. This is the current picture of the range covered by the ancient use of quinoa in this part of Argentina from its beginning some 4,500 years ago until Colonial times.

Hence, the enclaves located in the Puna, pre-Puna, and mesothermal valleys, as well as those close to the rainforests in the Northwest, outline a long-time regional counterpoint which accompanied the initial agricultural developments and continued until the Inca Empire. Such chronological continuity and the

Quinoa. A Millenary Grain in Northern Argentina, Fig. 10 Various pseudocereals sharing the same space within the high-elevation orchard of Rita Salva at Antofagasta de la Sierra, in the Punilla River basin (Southern Puna of Argentina)

geographical range of the ancient quinoa production in the region illustrate the presence of a rich and varied ancestral knowledge regarding variations in the agricultural and postharvest cycles and the seed in itself, which were adapted to the requirements of such differing landscapes. Further studies will prove if these statements are also true for the other geographical nodes in the western area of the Central-South Andes where quinoa was also in use: San Juan and Mendoza provinces in the Cuyo region.

Recent studies suggest that in northwestern Argentina, ecotone landscapes which define the transition between the typical highland and lowland environments would have been favorable for vegetal diversification. In the pre-Hispanic horticulture modes characterized by an open and flexible management of the flora, wild and domesticated plants, as well as weeds, may have shared the same agricultural fields, and their hybridization would have been accepted for different purposes (Lema, 2010). Quite possibly, quinoa would have been included in these production modes, as happens in some places nowadays (Fig. 10). At the time, there may not have been such a conclusive difference among plants producing panicles with edible grains as there is today. This situation is evident in the numerous

findings of diverse varieties of quinoa seeds mixed with *kiwicha* and grains of other plants classified as associated weeds.

To round off, wider knowledge is currently available regarding the pre-Hispanic chronology and geographical distribution of the cultivation, treatment, and consumption of quinoa in the modern Argentinian territory. However, a more precise knowledge of the insertion of these local practices in the larger panorama of the Central-South Andes is still pending, as is incorporating these data to the area where this grain was domesticated and intensively used. It is also necessary to study the historical reasons which led to the abandonment in its cultivation in most of the Argentinian territory, relegating it to the marginal position it has held until the recent past, a situation which nowadays seems to be improving.

Box 1: Quinoa Cultivation in the Past in Northwestern Argentina

Both cut stalks and panicles, as well as the large knapped knives used for reaping quinoa panicles in southern Puna, suggest that this plant was cultivated in the high-elevation desert at least some 3,500 years ago. It further seems to have followed a process similar to the modern one, with the exploitation of the spaces near permanent water sources (Hocsman, 2006). The plants would be managed through thinning or desuckering, and the ripe grains would be harvested by cutting the stalk. It is possible to make an analogy between the cut stalks and panicle fragment from Puna sites and the techniques still in use to harvest quinoa in some sectors of the Bolivian Altiplano. When the grain is in the appropriate maturity stage, the plants are cut at a certain distance from the soil. Panicles are removed from the fields after harvest, whereas roots and the basal part of the stalks remain planted. This strategy prevents soil loss, favors the manipulation of the panicles, and avoids the contamination of the unthreshed grain and later tasks with soil sediment (Escola, Hocsman, & Babot, 2013).

Desuckering is also optimal for harvesting the green leaves which can be used to cook warm or cold dishes such as soups or salads. This is what could have happened between 3,000 and 2,600 years ago in the Puna of Jujuy according to microscopic remains of leaves and the left-overs of food cooked in the now fragmented vessels from Cueva de Cristóbal site. As green leaves can only be harvested from growing plants, quinoa must have been cultivated near the residential areas in this Puna region of Jujuy (Babot, Hocsman, Piccón Figueroa, & Haros, 2012).

These many indications help reconstruct the pre-Hispanic production practices for quinoa. However, it is in the study of the ancient agricultural fields where the most direct evidence of this task can be found. In northwestern Argentina, the spaces devoted to seeding and harvesting in the past have turned out to be particularly elusive or badly defined, particularly due to the fragility and low recovery potential of quinoa remains from archaeological agricultural structures (López & Capparelli, 2010).

Fortunately, the study of diverse microscopic evidence such as pollen and other microfossils – started a little more than a decade ago – identified the first archaeoquinoas fields, dated to the beginning of the era. These fields are located in diversified environments in northwestern Argentina. One of them can be found in the hillsides of the high Catamarca valleys, testified by the microfossils identified in the soils of Morro Relincho site, where quinoa cultivation seems to have alternated with potatoes (Korstanje & Cuenya, 2008). A second enclave is the Chaco forest area bordering the eastern mountainous rainforest of Jujuy, topographically falling to 550 masl. There, quinoa cultivation was identified from the pollen recovered in Moralito site (Echenique & Kulemeyer, 2001). Beyond the geographic borders of

northwestern Argentina, pollen records indicative of the cultivation of quinoa and *kiwicha* extend to the late pre-Hispanic occupations in the Sierras Centrales, Córdoba, with a strategy similar to the one referred in seventeenth-century colonial documents (Medina, Grill, & López, 2008).

Corroborating the local cultivation of quinoa is important to clarify that at least some of the grain used in northwestern Argentina was self-produced, resulting from a three-millennium-old practice, rather than assuming that the seed came from the exchange of products with other areas of the Central-Southern Andes.

Box 2: The Ancient Uses of Quinoa

The traditional uses of quinoa plant in the pre-Hispanic past are found in the roots of practices still in use in some areas of northwestern Argentina (Storni, 1942). Studying the traditional postharvest treatment performed by modern Altiplano societies (López, Capparelli, & Nielsen, 2011), aimed at “improving” the grain and at the preparation of different products based on quinoa, has provided some analogical clues to recognize such treatments in archaeological contexts. It is also possible to record the modifications suffered by the seeds and other parts of the plant at both macroscopic and microscopic levels during these processes, as they leave identifiable traces on the archaeological material (Babot, 2003; López, Capparelli, & Nielsen, 2011). Hence, we know that, together with the first uses of this grain, procedures to eliminate the bitter compound (“saponins”) adhered to the seed pericarp or coat were implemented. This stage, which implied removing and winnowing the grain coat to later soak the grain in water and polish it with a piece of cloth, is fundamental for human consumption of quinoa.

Toasting may be further needed for certain extremely bitter varieties.

The grain prepared in this way would have served multiple purposes. Flour was obtained by grounding raw or cooked grains and may have been later used to knead dough or to thicken foods such as cold or warm soups or beverages, identified in the presence of microscopic seed remains. A substance similar to quinoa and *kaniwa* seed flour was preserved in the mills, pestles, and mortars used by the people living in the Punilla river basin and El Aguilar, in Catamarca and Jujuy provinces, respectively, from some 4,500 to 3,000 years ago (Babot, 2011; Babot, Hocsman, Piccón Figueroa, & Haros, 2012). Such preparations were also frequent in the nearby valleys and mountains, where flour remains were found on grinding stones of the agricultural societies inhabiting Tafí Valley and Amaicha del Valle, in Tucumán province (Babot, 2009). The propensity to pop of some of the grains also suggests that the seeds may have been placed among wild grasses near the hearths to produce a kind of popcorn. Popped quinoa was found in some sites of the Punta de la Peña location, in the Punilla river basin, at dates as early as 1,500 years BP (Babot, Aguirre, & Hocsman, 2013; Rodríguez, Rúgolo de Agrasar, & Aschero, 2006; Fig. 11). In this place, they were used both as a nutritive foodstuff and as an offering, embedded in ancient rituals. According to these records, the practice of toasting the seeds in straw beds with the occasional popping of the grain is rather old in the region, much prior to the arrival of the Incas.

Boiled grain preparations were also common in the Puna of Catamarca, seen in the agglutinated remains of seeds disposed in the garbage middens of the area (Babot, Aguirre, & Hocsman, 2013). However, it is in Cueva de Cristóbal (El Aguilar, Puna of Jujuy) where the exceptional

Quinoa. A Millenary Grain in Northern Argentina, Fig. 11 Pop quinoa from the Rockshelter 1 in the Punta de la Peña 9 site (1,500 years old), Punilla River Basin – the scale bar is in centimeters

preservation of an assemblage of fragmented pottery provided the most accurate evidence of food preparations or recipes based on quinoa at such an early date as 2,800–2,600 years BP (Babot, Hocsman, Piccón Figueroa, & Haros, 2012). These preparations included the use of quinoa grains as the only ingredient or, alternatively, their preparation as stews, porridges, or thick soups together with maize and tubers. Green leaves were probably used in soups or salads as well. In this way, wet culinary preparations with quinoa were routinely incorporated into the daily life of the groups inhabiting northwestern Argentina together with the first ceramic ware, supplementing the earliest consumption of this pseudocereal after toasting and grinding.

Together with the culinary uses of quinoa plants, the production and consumption of *llipta* was also frequent, at least from the beginning of the era. The *llipta* is an alkaline substance derived from the reduction of the plant to ashes. It is typically placed with coca leaves in the *acullico*. Its use during the past in northwestern Argentina seems to be indicated by the starch remains affected by heat and mixed with charred bone found in a small milling stone in the Los Viscos site, in El Bolsón Valley

Quinoa. A Millenary Grain in Northern Argentina, Fig. 12 Small lower grinding tool with calcined and grinded remains of bone and quinoa, probably to be used as *llipta* together with *coca* leaves – the scale bar is in centimeters

(Babot, 2009; Fig. 12). Microscopic remains of *llipta* and coca were also recorded in the dental calculus of the people living in Antofagasta de la Sierra during the first millennium AD, indicating that the *coqueo* was practiced by the time (González Baroni & Babot, 2013).

Other applications of the quinoa plant, such as using the stalks and roots for livestock fodder or fuel, as well as its reduction to ashes to prepare bleaches to wash wool, have not been deduced from archaeological materials so far. However, these uses may have been common in the past and could be identified in archaeological sites in the future.

Acknowledgments We would like to thank the researchers that shared unpublished material and photographs to be included in this article, Drs. Verónica S. Lema, Sara M.L. López Campeny, and Nurit Oliszewski, and also to Jacoba Morales, Julio Morales, Rita Salva, and many others who shared with us their traditional knowledge and expertise on quinoa.

Glossary

Chenopodium Genus which includes domesticated plant species such as quinoa, weeds such as “ajara” (*Chenopodium quinoa* var.

melanospermum), and wild species like “paico” (*Chenopodium ambrosioides*). Plants of this genus have small seeds of a similar morphology. Their appearance can be modified by several postharvest and charring treatments, making the precise identification of the species difficult during archaeological research and sometimes restricting it to the *Chenopodium* genus.

Microfossil Microscopic particle of animal or vegetal origin which constitutes a product of the metabolism of a living creature or a fragment of its tissues. It can survive after the decomposition of the individual they derive from, being useful as evidence when the complete specimen is absent. Microfossils include opal silica particles and crystal bodies of calcium salts (phytolites), starch grains, microcharcoal, pollen, and spores.

Panicle Quinoa inflorescence which presents a central axis as well as secondary and tertiary axes where the flowers of future seeds are inserted.

Pseudocereal Term used to designate the species of the genus *Chenopodium*, which includes quinoa and “ajara,” and *Amaranthus*, represented by *kiwicha* (*Amaranthus caudatus*) and other amaranths. The pseudocereal category discriminates these South American grains from maize and the cereals domesticated in the Old World, such as wheat and barley, by the place the starch is deposited in the seeds.

Thinning or desuckering Practice which consists in controlling the density of a crop by eliminating the excess of quinoa plants in the field, particularly the weak or small specimens, to gain much needed space for the better growth of the ones which remain.

Quipu

Molly Tun

University of Minnesota, Minneapolis, MN, USA

The quipu is most commonly known as the numeric recording system of the Inca Empire, which extended across Peru and parts of Chile, Argentina, Ecuador, Bolivia, and Colombia during the fifteenth and sixteenth centuries (see Fig. 1). This device is the result of a long tradition of Andean textile production and string patterns in pre-Inca civilizations, and its use extended well into the colonial period (and is still used to some extent in various present-day communities). Over the years, these knot records have been interpreted as mnemonic devices, numeric

Quipu, Fig. 1 An Inca quipu from the southern coast of Peru (Courtesy of the Milwaukee Public Museum)

accounts, narrative histories, binary codes, and various classifications of writing systems.

Colonial chroniclers described their awe and inability to perceive how the Incas manipulated the colored cords with such ease to denote both numerical and historical information related to the tribute of goods and money, labor obligations, censuses, laws, past leaders, and deposits. The Jesuit missionary José de Acosta writes,

They are quipus, memorials or events registered in strings, on which diverse knots and diverse colors, meant different things. It's incredible what they achieved this way, how much books can say about history, and laws, and ceremonies, and business accounts. The quipus supply all this so promptly that it's admirable. In order to have these quipus or memorials there were official representatives that today are called *quipocamayo*, who were obligated to give accounts of everything, like the public scribes here, and as such they have to be given full credit. For diverse genres like war, government, tribute, ceremony, land, there were diverse quipus or strings. And in each handling of these, so many knots and intricacies, and strings were attached. Some were colored, some green, some blue, others white, and so many differences, that just as we form 24 letters in different ways and make such an infinity of words, these knots and colors make innumerable meanings of things (VI. c. viii. 2008, p. 210 my translation)

Colonial accounts such as this one, however, cannot be taken as verbatim descriptions of Inca

Quipu, Fig. 2 Images of quipus and quipucamayocs from the *Nueva coronica y buen gobierno* by Guamán Poma de Ayala (1615), folios 202r, 335v, 348r, 358r, 360r, 773r, and 700r

Quipu, Fig. 3 Images of quipus and quipucamayocs by Martín de Murúa, folios 76v and 124v from *Historia y Genealogía de los Reyes Incas del Perú*, Galvin Manuscript (1590), and folio 51v from *Historia General del Piru* (1616) Getty Manuscript, Ms. Ludwig XIII 16 Los Angeles, J. Paul Getty Museum

Quipu, Fig. 4 This is a contemporary replica of a quipu composed of commercial yarns. Its cords contain the information regarding the final grades submitted to the registrar of the past 15 courses taught by the author at the University of Minnesota in the past 5 years (Photo by author)

accounting as this practice and the very nature of quipus were greatly transformed after Spanish intervention (Curatola Petrocchi & de la Puente Luna, 2013). To my knowledge, there are ten known images of quipu from the colonial period, seven from the *Nueva corónica y buen gobierno*, two from the *Historia General del Piru* (Galvin Manuscript), and one from the *Historia General del Piru* (Getty Manuscript) (Figs. 2 and 3). These visual sources provide additional clues regarding the system including the connection between quipu records and the Spanish letter: *carta*, the Inca messengers; *chasquis*, the Inca deposits; *collca*, the Inca abacus; *yupana*, astronomy, the Spanish book; and more.

On a descriptive level, the quipu is a system of cords and knots in which information is conveyed through the varied use of knot patterns, materials, and structural indicators (Fig. 4). In its most basic and common form, the quipu is composed of a thicker primary cord from which pendant cords are attached in a downward direction and top cords extend upward, sometimes even uniting various pendant cords. Each cord is at least two ply with one looped end and one finished with a knot. Subsidiary cords can be affixed to any top or pendant cords or even to other subsidiary cords. This structure of main, pendant, top, and subsidiary cords of distinct colors and adornments is

Quipu, Fig. 5 Details of the single knot, figure-eight knot, and long knot with three turns (Photo by author)

Quipu, Fig. 6 Figure-eight knot and long knots #2-9 (Image by author)

Quipu, Fig. 7 Single knots #1-9 (Image by author)

Quipu, Fig. 8 A replica of the knot pattern described by Locke, illustrating cord summation, $134 + 366 + 250 + 55 = 805$ (Image by author)

created before knots are tied into the medium (Ascher & Ascher, 1981, p. 21). The figure-eight knots (representing #1) and the long knots (representing #2-9) are used in the units position, and the single knots (representing #1-9) are used in all other place values (tens, hundreds, thousands, etc.) (Figs. 5, 6, and 7). This positional system locates the highest place values closest to the primary cord with the units position toward the end of the cord, and 0 is represented by a blank space in any of these positions. The use of the numbers 0–9 is indicative of a base-10 counting system, and this conjecture was confirmed in 1923 by Leland Locke, who showed that a decimal reading of the knots of four pendant cords revealed that their summation was

located on the top/summation cord that united them, a logical and common relationship of quipu cords (Fig. 8).

After reading knots as numeric values in base 10, various scholars have attempted to correlate their numeric values with qualitative data registries. After examining quipus from burial sites, Erland Nordenskiöld (1925) claimed that only quipus reflecting the cosmos with mysterious religious, astronomical, and calendrical data could be buried alongside the deceased, and Day's analysis of quipus 14–3866 (“the astronomer’s notebook”) also suggests the astronomical data such as lunations and synodic revolutions of Mercury, Venus, and Jupiter were recorded on the quipus. “Such efforts have not, however, proved convincing to succeeding researchers, since the ‘proofs’ characteristically involved a careful sifting and arranging of both astronomical and quipu numbers until coincidences were formed, with the remaining bulk of numbers unexplained” (Conklin, 1982, p. 263). More recently, Robert and Marcia Ascher, Tom Zuidema, and Gary Urton identified quipus whose cord values resemble calendrical data (Ascher & Ascher, 1978; Urton, 2011b; Zuidema, 1988). This decimal interpretation of the knots has been widely accepted, although not all quipus found have this same pattern of knots (Adawi Schreiber, Ortegá Izquierdo, Mejía Pérez, & Rojas Leiva, 2011).

The first effort to centralize quipu descriptions on a large scale is that of Robert and Marcia Ascher, who recorded the following categorical data from 206 quipus (from 1970 to 1988): knot type and placement, cord type, placement, length, color and attachments, and numerical interpretations (<https://courses.cit.cornell.edu/quipu/contents.htm>). The Ascher model has been used and modified in subsequent data collection projects, including that of Gary Urton (2002–2009), who also examined twist and knot direction and cord attachment (<http://khipukamayuy.fas.harvard.edu/>), Hugo Pereyra (2006), who initiated a Peruvian database, and the National Museum of Archaeology, Anthropology and History in Lima, Peru (Adawi Schreiber et al., 2011), which began Project Quipu in 2007 with the objective of describing their quipu archive (of over

Quipu, Fig. 9 Quipu-keepers from Tupicocha, Perú (Photo reproduced with permission of the Archive of the Ministry of Culture, Peru)

200 samples). Gary Urton and Carrie Brezine used software programs to comb through the Harvard database, looking for matching quipus that shared a similar external structure; they found that some of the Puruchuco quipus displayed the summation values of other local quipus, concluding that information was assimilated throughout the empire, either being funneled and synthesized upward or subdivided and distributed downward. Urton and Brezine also suggest that the introductory cords on the local quipus served as location identifiers used when moving information throughout the empire (Urton & Brezine, 2005).

In addition to archival research, scholars have carried out fieldwork in communities that use “modern” quipus in order to illustrate the great variety of quipu manifestations that exist and possibly have some connection to ancient traditions (Mackey, 1970; Ruiz Estrada, 1981; Uhle, 1897). Frank Salomon, together with the Ministry of Culture (Peru), has made available a documentary entitled *Tierra de Quipus* in order to illustrate these contemporary quipu traditions in the

Quipu, Fig. 10 Sabine Hyland with a quipu board from Mangas, Peru (Photo reproduced with her kind permission)

Peruvian village of Tupicocha: <https://www.youtube.com/watch?v=xjEzFW4IUBs> (Fig. 9).

The enigmatic nature of this particular accounting tool stems ultimately from the difficulties inherent in preservation of the quipus themselves as well as the ability to read their encoded messages. The number of quipu samples identified to be in existence is estimated to be around 800 (Urton, 2011a, p. 65), the majority of these being cotton samples from the arid coastal region of Peru where preservation conditions are maximal; far fewer samples of camelid knots from this central region of Peru have been traced. But perhaps even more consequential to our understanding of this medium is the loss of the knowledge that would allow scholars to decode and “read” the knot messages. While the loss of this ancient counting practice is oftentimes attributed to destructive colonial policies and the introduction of alphabetic writing in the Andes in the sixteenth century, one colonial document suggests that the destruction of this

medium actually commenced during the civil war of the Inca Empire when the captains of the aspiring Inca leader Atahualpa “killed all the quipucamayos that they could get their hands on and burned their quipus saying that they had to start over again” (Collapiña & y otros quipucamayos, 1974, p. 20 my translation) in order to erase the memory and record of previous Inca leaders. In spite of the difficulties, scholars continue working to uncover the lost legacy and past entwined in the quipu cords – a task that might be accomplished through further analysis of the quipu boards that juxtapose the colored cords and alphabetic print, exhibiting the distinct mediums side by side (see Hyland, Ware, & Clark, 2014) (Fig. 10).

Qusṭā ibn Lūqā

E. Ruth Harvey

Qusṭā ibn Lūqā is one of the important figures in the transmission of Greek scientific writings to the Muslim world and subsequently to the Latin west. The ancient Arab biographers say that he was a Christian of Greek origin from Baalbek (Heliopolis) in Lebanon; he visited the Byzantine empire and brought back Greek texts which he then translated into Syriac and Arabic. He worked for the Caliph al-Mustaʿīn (862–866) in Baghdad, where he may well have known ► [al-Kindī](#) and Thābit ibn Qurra; he died in Armenia (ca. AD 912/300 AH) where he had been an honored guest of the ruler Sanharib.

Qusṭā is important both for his translation and for his original works. The transition of Greek science and philosophy into the Arab world resulted in the development and preservation of traditions largely lost to the west. Most western medieval science owes a great debt to the Arab scholars who kept alive this vital link with ancient learning. Qusṭā provided versions of Diophantos' *Arithmetica*, Hypsicles' *Liber... de ascensionibus*, Autolycus' *De ortu et occasu*, Theodosius of Bithynia's *De sphaeris*, and Hero of Alexandria's *Mechanics*; Qusṭā's Arabic version of this last work is the only text extant today. He is credited with other translations, notably some of the works of Aristotle with the commentaries of Alexander of Aphrodisias and John Philoponos, but they do not appear to have survived.

The biographers provide a list of over 60 original works by Qusṭā; the titles suggest that most are medical, but some are clearly works on mathematics, astronomy, logic, and natural science. Sezgin provides a list of the medical works of Qusṭā which are known to survive in manuscript. Very few of them have been printed, although interest in Qusṭā's treatises is increasing. His little monograph on infection (*Kitāb fī al-īdā'*) explains in terms of the medicine of the day how some diseases are contagious, and his *Viaticum*, explaining various principles of health and hygiene for travelers are both now available. His work on sex has been published in Germany, but is not readily obtainable. A work on the efficacy of amulets is extant only in the Latin translation of Arnald of Villanova (called both *De physicis ligaturis* and *De incantatione*); the Arabic text of his work on the celestial globe still exists and there are in addition medieval translations of the treatise in Latin (*De sphaera solida*), Hebrew, Spanish, and Italian.

Probably the most famous and influential of all Qusṭā's works is the short treatise on the difference between the spirit and the soul (*Kitāb fī 'l-farq baina 'l-nafs wa 'l-rūh*), which,

in the Latin translation of John of Seville, was used as an authority by almost all medieval Western physicians and by some of the philosophers. It distinguishes carefully between the immortal soul and the bodily "spirit of life" within man. The idea that a material but gaseous substance existed inside the human frame and made possible the functions of life, sensation, and motion was an essential part of medical doctrine in the days before the discovery of electricity. Qusṭā's lucid explanation was received as a kind of gloss or commentary on Aristotle's *De anima*. It was frequently misattributed to Constantine the African.

R

Rainwater Harvesting

Arnold Pacey

Throughout history people have lived in areas where there are few rivers and where the direct collection of rainwater from roofs, paved courtyards, hillsides, or rock surfaces is one of the best available methods for securing a water supply. By extending this principle to provide water for crops, early civilizations practiced agriculture much further into the semidesert areas of Arabia, Sinai, North Africa, India, and Mexico than has been possible in modern times – and this is not explicable by changes in climate.

Agriculture in the Old World originated in climatically dry regions in the Middle East and may have depended to some degree on rainwater running off nearby slopes almost from the start. Evidence is lacking until a later period, however, when some of the most striking applications of rainwater harvesting were related to crop production in the Negev Desert between 200 BCE and AD 700. One technique would be to dig a channel across a hillside to intercept water running downslope during storms. The water would be directed onto fields which, in the Negev, were carefully leveled and enclosed by bunds (an embankment or dike). Further west, steeper hillsides were used in Morocco, with cultivation on flat terraces formed behind stone retaining walls. In Tunisia,

French travelers in the nineteenth century noted fruit trees being grown at the downslope end of small bunded rainwater catchment areas or microcatchments.

In India, one common technique is simply to build a bund across a gently sloping hillside, so that runoff flows originating from rainfall collect behind the bund, where water is left standing until the planting date for the crop approaches; then the land is drained, and the crop sown. This land behind the bund which is seasonally flooded and then later planted with a crop is known as an *ahar* in Bihar, or a *khadin* in Rajasthan. Although some *ahars* may be only 1 ha in extent with a bund 100 m long, others are very large and account for 800,000 ha of cultivation in Bihar state. In desert areas of Rajasthan, there are many *khadins* of 20 ha or more, some of them having been first constructed in the fifteenth century AD.

In North America, research on the modern potential of runoff farming methods has been stimulated by the realization that people living in what is now Mexico and the southwestern United States prior to European settlement had methods of directing rainwater from hillsides on to plots where crops were being raised, thereby making productive agriculture possible in an otherwise unpromising semiarid environment. On lands occupied by the Hopi and Papago peoples in Arizona, fields were predominantly on alluvial valley soils below hillsides or gullies from which water could flow to the crops during rainstorms.

Sites were chosen so that only minimal earth-works were needed to spread the water over the fields. These were short lengths of bund referred to as spreader dikes.

Raja Ratan Singh

S. M. Razaullah Ansari
Aligarh Muslim University, Aligarh, UP, India

From the reign of Emperor Akbar (1556–1605), when a common syllabus for rational sciences for madrasas was introduced, the madrasas in India became institutions in which Muslim and Hindus together acquired their higher education without any prejudice. In this article, India denotes Medieval India. Raja Todar Mal, the minister of Emperor Akbar, was directed to promulgate in 1582 the decree by which the local language Hindi was replaced by Persian as the official language of administration and thereby motivated the Hindu officials (*Munshīs*) and scholars to learn Persian. In fact the learning of Persian among Hindus had already been promoted by Sultan Zainul 'Ābidīn (r. 1423–1474) in Kashmir and Sultan Ibrāhīm Lodhī (r. 1517–1526) during the Sultanate period in North India. Both Muslim and Hindus attended *madrasas* and also joined

instruction (*Darāsāt*) offered privately by famous Muslim scholars and poets, in order to learn Persian and to study other disciplines ('*Ulūm*'). Later arose a whole Hindu caste, *Kāyesth*, which became gradually expert in both the Persian language and literature. Actually the *Kāyesth* community in Medieval India contributed to many disciplines: poetry, history, anthologies of poets (*Tadhkirah*), epistles (*Inshā*), philosophy, Islamic medicine, mathematics, astronomy, and lexicography. Evidently this writer-caste, *Kāyesth*, became very influential in the courts of Mughal emperors, predominantly during the reign of Muḥammad Shāh (171–1749) and his successors and even in the administration of local rulers. Hindu *Munshis* gradually dominated the Persian-knowing community of Mughal officialdom. In this article, I wish to present the scientific contributions of the Hindu poet, writer, historian, and particularly astronomer, Raja Ratan Singh Zakhmī (d. 1851).

Biography

Raja Ratan Singh (1782–1851) s/o Rai Balk Ram Kayesth, born in Lucknow, belonged to an illustrious family of servicemen of the *Nawābs* (rulers) of Awadh (modern *Uttar Pradesh*). His grandfather, Raja Bhagavan Das, was the *Dīvān* (prime minister) of Āṣaf-ud-Daulah (r. 1775–1797). Ratan Singh began as a servant of the East India Co. at Calcutta (ca. 1803), and after 1815, he joined the court of the Awadh rulers: Ghāzīuddīn Ḥaidar (r. 1814–1827), Naṣīruddīn Ḥaidar (r. 1827–1837), and Muḥammad 'Alī Shāh alias Naṣīr-ud-Daulah (r. 1837–1842). This last Nawāb bestowed on the Raja the title, *Fakhr-ud-Daulah Dabīrulmulk Hoshyār Jang* (Pride of his Kingdom, Secretary of Administration and Intelligent Veteran).

Ratan Singh was a scholar of many languages: Arabic, Persian, Turkish, Sanskrit, and also English. He studied the traditional disciplines ('*Ulūm-i Naqliya*) and the rational sciences ('*Ulūm-i 'Aqliya*). He is known as a *litterateur*, with his *nom de plume* *Zakhmī* (the wounded), a historian, and an excellent scholar of astronomy.

In this article, we report on two of his astronomical works. For his poetic compositions, historical works, etc., see Storey (1972), Vol. I (pt. 1), p. 709, and Ansari (2004) pp. 130.

Mi'yār al-Azmān

Mi'yār al-Azmān is a short tract on chronology completed in ca. 1819, which deals with calendars (*Tawārīkh*) of different nations: Arab/Hijrī, Christian, Roman, ancient Persian (*Yazdijird*), Jalālī or Malikshāhī, ancient Indian, Chinese, Greek, Coptic, and Khānī. The various epochs, i.e., beginning date of each era, are explained clearly. Moreover, he gives comparative tables for various eras for the year 1234 AH/1819. According to our preliminary survey, four manuscripts of this tract are extant, one each in the Asiatic Society (Calcutta, modern Kolkata), Khuda Bakhsh Library (Patna), and the Library of Urdu Promotion Board (*Anjuman Taraqqī-i Urdu*), Karachi. The manuscript copy at Raza Library (Rampur) is ascribed by Ghulām Hussain and dated 1822. No study of this tract is known so far.

Hadā'iq al-Nujūm (Gardens of Astronomy)

Hadā'iq al-Nujūm: Gardens of Astronomy is a comprehensive compendium in Indo-Persian on nineteenth-century European astronomy, which includes its mathematical treatment; it will be referred to hereafter as HN. Ratan Singh completed this treatise in 1837 by the order of Nawāb Muḥammad 'Alī Shāh alias Naṣīr-ud-Daulah. It was lithographically printed and published in a few editions, 1837, 1841 (Lucknow), and 1843 (Storey II (1) p. 99; Rahman p. 350). Four manuscript copies of the treatise are extant in M.A. Library (AMU, Aligarh), along with a copy of the Lucknow edition. This systematic treatise consists of nine chapters (*Hadīqa*, Arabic for garden) with 1158 pages and comprises 180 tables (*Lawḥ*) and 129 diagrams (*Shakl*). The author states in the beginning that he “describes in this book the celestial bodies,

solution of their astronomical problems according to the past Islamic scholars and present European scholars and also some researches of his own” (p. 8). The European scholars are Copernicus (1473–1543), Tycho Brahe (1546–1601), Galileo (1564–1642), Kepler (1571–1630), and Newton (1642–1727). He also describes recent works of Hevelius (1611–1687), Flamsteed (1646–1720), Herschel (1738–1822), Cassini (1625–1712), and Lalande (1732–1807), to name just a few. Ratan Singh's collection of these sources is remarkable indeed in nineteenth-century India. Modern instruments treated in HN are the telescope (*Dūrbīn*, *Sitārahbīn*), the micrometer (*Raizah-i Paimā*), and cross wires (p. 154). Ratan Singh gave a short history of the telescope. He stated that Johann Lippershey invented and constructed a telescope of 15 in. in 1590; the telescope of Zakaria Jansen was of 18 in. in length and was made in 1605. He mentioned also in this connection Simon Marius, Galileo, and Kepler (p. 152). He describes the establishment of the Greenwich observatory in 1676 and the Paris observatory in 1664 (p. 156). Ratan Singh treated in detail in a chapter/section the following salient features of European astronomy, which are cited here in Ratan Singh's own words:

1. The Sun is a member of fixed stars, it is a source of light (*Nūr*) and heat and gives its light to all planets and comets (HN p. 181).
2. Proof that the Sun is stationary (pp. 188–190). Besides the gravitational attraction, Ratan Singh discusses the phases (i.e., the variation in shape) of Mercury and Venus and also their transits across the disk of the Sun as the proof of the heliocentric system. See the data for transit of Venus and Mercury in Table 1.
3. The orbits of all planets, satellites, and comets are all elliptical. . . with the Sun at one focus. He deals with gravitation, true, and mean anomaly (HN pp. 135, 188, 222).
4. In a diagram of the solar system, he draws the orbits of planets around the Sun including orbits of satellites (*qamar*) of major planets in this sequence: Mercury, Venus, Earth (1 satellite), Mars, the minor planets (Vesta, Juno,

Raja Ratan Singh, Table 1 Data for transits of Venus and Mercury

Table no.	Page no. ^a	Concerning	Remark/period/sources
58	363–367	Obliquity (60 values)	As determined by Ancient Indian (1), Greek (5), Islamic (13), and European (41) astronomers
49	298–305	Transits of Mercury	AD 1605–1894
51	310–315	Venus	AD 902–2984 ^{b1}
	312	Venus	7 June 2004, 5 June 2012, 10 Dec. 2117 ^{b2}
109	709–722	Lunar and solar eclipses	AD 1837–1900
112	776–799	Comets	AD 835, 1231–1835 ^c

133	1,000–1,004	Planetary revolutions in a <i>Kalpa</i>	Sanskrit sources: <i>Brahāmasiddhānta</i> , <i>Pancasiddhānta</i> , <i>Sūryasiddhānta</i> , etc.

^aRefer to Ratan Singh's Treatise: *Hadā'iq al-Nujūm*

^{b1}Source: de Laland, *Astronomie* (Paris), probably the first edition of 1764. He also mentions that "Ibn Sīnā (d. 1037), Abū 'Imrān in Baghdad, Muḥammad abī Bakr observed Venus on the face of the Sun, [while] Ibn al – Māja and Ibn al – Haitham (d. 1039) observed *Venus* and *Mercury* each as black dot on the disk of the Sun" (p. 309), cf. Goldstein (1985), Kapoor (2013)

^{b2}Venus transit occurs in pairs. The dates of the first pair are correct. Of the second pairs, Ratan Singh has given only one correct date, the second date is Dec. 2125; see www.wikipedia.org/wiki/Transit_%20of_%20Venus, accessed on 26.8.14

^cThis is the Halley comet for which he mentions its earlier sightings and his own observation first on 15 Oct. 1835 near *Corona Borealis* (in Persian *Ikhlī Shimālī*) with the length of its tail between 29° and 30° and its period being 76 years and 248 days (p. 805). For more tables, see Ansari (2006)

Ceres, and Pallas), Jupiter (4), Saturn (7), and Uranus (6), the last one he calls *Jarjīs*. F. W. Herschel discovered Uranus in 1781. He named it *Georgium Sidus* after the King of England George III. The name *Jarjīs* is derived from George. The German astronomer J. E. Bode named this seventh planet of our solar systems Uranus, which name gained currency in about 1850 (*HN*, p. 180). Ratan Singh named these in the correct order of ascending heliocentric distances. See Fig. 1, which is the reproduction of his diagram No. 85.

- On comets. I reproduce here in Fig. 2 Raja Ratan Singh's observations of sunspots furnished with umbra and penumbra and drawings of three comets (*HN*, diagram No. 57, p. 178). The Persian text reads in Fig. 2 as follows: The first diagram of the comet below the solar disk is the picture of Halley's comet, which he observed in 1835 AD, and he found its period of revolution (*Dawr*) as 76 years and 248 days. Raja Ratan Singh gives two further drawings of comets: one with a small tail observed in 1819 by Sir John Herschel, who calculated its period as

1,207 days, but according to Dolhaus was only 1,203 days, and the third comet without a tail was observed actually by Biela in 1826 and again in 1832. Raja Ratan Singh gives the period of this comet as 2,427 and 2,469 days, citing the calculations of Gambart and Dolhaus respectively. The chapter on comets is very detailed one (*HN* p. 730–829). There is a full section on Halley's comet (*HN* pp. 805–810); see Table 1 (row 5).

Raja Ratan Singh's *Treatise* in Persian of 1157 pages is in fact a unique comprehensive compendium of nineteenth-century European practical astronomy, in which elements of traditional ancient Indian and particularly of Islamic astronomy are *not* overlooked. The important discoveries of eighteenth-nineteenth centuries have been particularly well treated, for instance, about asteroids, planetary configurations, or the solar system according to Ptolemy, Tycho Brahe, Regiomontanus, and Copernicus and even about nebulae after Herschel (*HN*, pp. 1006–1027). The treatise was printed in three editions (1837, 1841, and 1843) and published in Lucknow, the capital

Raja Ratan Singh, Fig. 1 Diagram of heliocentric system. Orbits of major and minor planets: Mercury, Venus, Earth (1 satellite), Mars, Vesta, Juno, Ceres and Pallas, Jupiter (4), Saturn (7), and Uranus (6), the last one is named *Jarjīs*. Cf. Text, section 2.4, (HN, p. 180)

Raja Ratan Singh, Fig. 2 Solar disk with sunspots and three comets: Halley (1835), Herschel (1819), Biela (1832). Cf. Text, section 2.5

of the rulers of Awadh state, which was then bustling with the confrontation of traditional and modern scientific culture. As evidence the following instances are noteworthy.

The Frenchman Claude Martin (d. 1800), who was in the service of the Awadh ruler (*Nawāb*), Aṣaf -ud-Daulah (r. 1775–1797) at Lucknow, was extremely interested in European scientific pursuits and devices, e.g., steam engine for raising water out of wells and telescopes for his private observatory, one of which he bought from the astronomer royal, William Herschel. He had been a major general in the French Army initially and later shifted his allegiance to the British East India Co. Inspired by Martin's observatory, the geographer Khaliluddīn Khān built an observatory in 1820 to teach practical astronomy (Khan, 2003, pp. 288–289; Liewellyn-Jones, R. (2004)).

Nawāb Naṣīruddīn Ḥaidar (r. 1814–1827) founded the Royal Observatory at Lucknow.

Maj. Richard Wilcox (d. 1848) was appointed in 1835 as the director, whose observational work on minor planets during 1840–1846 became well known internationally. Unfortunately that observatory was abolished in 1849 by Nawāb Wājīd ‘Alī Shāh (r. 1847–1856), cf. Ansari (1985), pp. 385–389.

From 1815, when Ratan Singh joined the service of the Nawab of Awadh, he had been a witness to all this development. It is therefore not surprising that Nawāb Naṣīr-ud-Daulah alias Muḥammad ‘Alī Shāh (r. 1837–1842) commissioned Ratan Singh to write a treatise on mathematical and practical astronomy which I consider the culmination of the “Awadh scientific

renaissance” (Khan, 2003, pp. 287–292). Unfortunately that nascent reawakening was stifled in the bud, when Persian and Urdu languages were banished from the curricula of schools and replaced by English as the medium of instruction by the British Colonial Government.

Ramanujan

Bruce C. Berndt
Urbana, IL, USA

Srinivasa Ramanujan was born on 22 December 1887 in the home of his maternal grandmother in Erode, India, a small town located about 250 miles southwest of Madras. Soon thereafter, his mother returned with her son to her home in Kumbakonam, approximately 160 miles south-southwest of Madras. Ramanujan’s father was a clerk in a cloth merchant’s shop, and his mother took in local college students to augment the family’s meager income.

Ramanujan’s mathematical talent was recognized in grammar school, and he won prizes, usually books of English poetry, in recognition of his mathematical skills. At the age of 15, Ramanujan borrowed G. S. Carr’s *Synopsis of Pure Mathematics* from the local Government College in Kumbakonam. This unusual book, written by a Cambridge tutor to teach students, contained approximately 5,000 theorems, mostly without proofs, and was to serve as Ramanujan’s primary source of mathematical knowledge.

With a scholarship, Ramanujan entered the Government College in Kumbakonam in 1904. However, by this time, he was completely absorbed with mathematics and would not study

any other subject. Consequently, at the end of his first year, Ramanujan failed all of his exams, except mathematics. He lost his scholarship and therefore was unable to return to college.

For the next 5 years, working in isolation, Ramanujan devoted himself to mathematics. He worked on a slate, and because paper was expensive, recorded his mathematical discoveries without proofs in notebooks. During this time, he attempted once more to obtain a college education, at Pachaiyappa College in Madras, but his singular devotion to mathematics, and illness, deterred him again.

Having married Janaki in 1909, Ramanujan sought employment in 1910. For over a year, he was privately supported by Ramachandra Rao, as he gradually became known in the Madras area for his mathematical gifts. In 1912, Ramanujan became a clerk in the Madras Port Trust Office, and this was to be a watershed in his career, for the manager, S. Narayana Aiyar, and the Chairman, Sir Francis Spring, took a kindly interest in Ramanujan and encouraged him to write English mathematicians about his work.

On 16 January 1913, Ramanujan wrote to the famous English number theorist and analyst, G. H. Hardy. He and his colleague J. E. Littlewood examined the approximately 60 mathematical results communicated by Ramanujan and were astounded by his many beautiful and original claims. Hardy strongly encouraged Ramanujan to come to Cambridge, so that his mathematical talents could be fully developed. At first, Ramanujan was reluctant to accept the invitation, because of orthodox Brahmin beliefs that crossing the seas makes one unclean, but on 17 March 1914 Ramanujan sailed for England.

During the next 3 years Ramanujan achieved worldwide fame for his mathematical discoveries, some made in collaboration with Hardy. However, in the spring of 1917, Ramanujan became ill and was confined to nursing homes for the next 2 years. Tuberculosis, lead poisoning, and a vitamin deficiency were among the many diagnoses made, but a more recent examination of Ramanujan's symptoms points to hepatic

amoebiasis. In 1919, he returned to India with the hope that a more favorable climate and more palatable food would restore his health. However, his condition worsened, and on 26 April 1920, Ramanujan passed away.

After Ramanujan's death, Hardy strongly urged that Ramanujan's notebooks be edited and published with his *Collected Papers*. Two English mathematicians, G. N. Watson and B. M. Wilson, devoted over 10 years to proving the approximately 3,000–4,000 theorems claimed by Ramanujan in his notebooks, but they never completed the task. It was not until 1957 that an unedited photocopy edition of Ramanujan's notebooks was published. In 1977, Berndt, with the help of Watson and Wilson's notes, began to devote all of his research efforts toward editing the notebooks, and in 1998 he completed the task with the publication of his fifth volume on the notebooks. In 1976, Andrews discovered a sheaf of 140 pages of Ramanujan's work, now called the "lost notebook," in the library at Trinity College, Cambridge. In 2005, Andrews and Berndt published their first volume on Ramanujan's lost notebook.

Ramanujan made many beautiful discoveries in several areas of number theory and analysis, in particular, the theory of partitions, probabilistic number theory, highly composite numbers, arithmetical functions, elliptic functions, modular equations, modular forms, q -series, hypergeometric functions, asymptotic analysis, infinite series, integrals, continued fractions, and combinatorial analysis. His influence can be traced to many areas of contemporary mathematics; this is evident in the proceedings of major conferences commemorating Ramanujan on the 100th anniversary of his birth. Although much of Ramanujan's work is quite deep, many of his original discoveries can be understood with a background of only high school mathematics. In particular, his several results on solving systems of equations, representing integers as sums of powers, and approximating π are elementary. In the past few decades, as more of Ramanujan's results have been unearthed, his already great reputation has soared even more.

Most biographical sketches of Ramanujan's life rely chiefly on the obituaries written by Seshu Aiyar and Ramachandra Rao, and the writings of Hardy. However, Robert Kanigel's biography is by far the most complete and detailed description of Ramanujan's life. Much can also be learned from Ramanujan's letters to Hardy, his family, and friends.

Ramat Raḥel

Oded Lipschits

Institute of Archaeology, Tel Aviv University,
Tel Aviv, Israel

Ramat Raḥel (Heb. רַמַּת רָחֵל) is an ancient site located on a hilltop (818 m above sea level), about midway between the Old City of Jerusalem and Bethlehem. It is inside Israel's international 1947–1948 borders in the western part of Kibbutz Ramat Raḥel. The site is located in one of the highest peaks to the south of Jerusalem, a location that offers a superb view to the north (Mount Zion and modern-day western Jerusalem), to the west (the Rephaim Valley), and to the south (Mount Giloh, Bethlehem and the northern Judean hills). This is also a prominent strategic place, controlling the important junction between the "King's Road" leading from Jerusalem southward, in the direction of Bethlehem, Hebron, and Beersheba, and the road leading from Jerusalem westward, in the direction of Beth Shemesh in the Shephelah, through the Rephaim Valley. Furthermore, Ramat Raḥel has complete control over the Rephaim Valley, with its rich alluvium soil and moderately terraced slopes, one of the prosperous agricultural districts in the Jerusalem landscape, vital to the economy of the city, a valley that probably should be identified with the Biblical "Valley of the King" (Fig. 1).

The Arabic name of the site is Khirbat Ṣāliḥ, but the name and the identification of the site during the Biblical period are still an enigma. Based on the LXX supplement to Joshua 15: 59a and on Nehemiah 3: 14, Yohanan Aharoni identified Ramat Raḥel as the Biblical Beit Hakerem. He hypothesized that the site was built on a previous vineyard of the king and this is the source for its name. This suggestion was accepted by most scholars, even though Benjamin Mazar suggested identifying the site with Netofah, a site mentioned in the Old Testament near Bethlehem (2 Sam 23: 28; 1 Chr 2: 54, et al., and cf. Ez 2: 22; Neh 7: 26; 12: 28), and Gabriel

Ramat Raḥel, Fig. 1 Map of the area of Ramat Raḥel (Ido Koch, based on the PEF Map)

Ramat Raḥel, Fig. 2 Reconstruction of Ramat Raḥel and its edifice as seen from the southwest (Drawing by Nirit Kedem)

Barkay identified the site with MMŠT [the Hebrew letters Mem-Mem-Shin-Tav] – one of the places mentioned on the LMLK stamp impressions [LMLK, in Biblical Hebrew, “belonging to the king,” are stamp impressions on jar handles, identified as part of the royal system of jars in Judah, mainly from the time of King Hezekiah. See below an image of this stamp impression as well as other types of stamped jar handles from Judah].

In 1930–1931, B. Mazar and M. Stekelis excavated a Jewish burial cave some 200 m to the south of the site’s hilltop on behalf of the Israel Exploration Society. Y. Aharoni excavated the hilltop in 1954 and again in four successive seasons between 1959 and 1962 on behalf of the Israel Department of Antiquities and Museums, the Israel Exploration Society, the Hebrew University of Jerusalem, and the University of Rome. G. Barkay made a few soundings at the site in 1984 on behalf of the Institute of Archaeology of Tel Aviv University, the Israel Exploration Society, the Israel Department of Antiquities and Museums, and the American Institute of Holy Land Studies on Mount Zion. In the framework of the site’s restoration and reconstruction as an Archaeological Park, Gideon Suleimanny, on behalf of the Israel Antiquities Authority, made trial excavations. Excavations on behalf of the Institute

of Archaeology of Tel Aviv University and the University of Heidelberg resumed in 2004, under the direction of O. Lipschits, M. Oeming, and Y. Gadot, as part of a major excavation project. Between 2005 and 2010, six excavation seasons were conducted in the site by hundreds of students and volunteers. In addition, a comprehensive survey of underground spaces, a survey of agricultural installations and a comprehensive study of the agricultural terraces on the slopes of the mound were carried out.

Based on the results of the Renewed Expedition and the careful study of the previous excavations conducted at the site, it seems that at Ramat Raḥel there are nine separate phases of construction and development and additional phases of destruction and desolation (Figs. 2 and 3).

Prior to the late eighth century BCE, the hill was rocky and desolate, with no evidence of human habitation. **The first building phase** should be dated to the late eighth to early seventh centuries BCE. The main structure from this early phase is the “western tower.” In its plan and building method, the tower belongs to the array of fortresses built on high hills around Jerusalem in the late Iron Age. Other structures from this building phase were later either incorporated into structures of the following phase or dismantled to their foundations, and it is difficult to understand the architectural plan of this phase. However,

Ramat Raḥel, Fig. 3 General plan of Ramat Raḥel (Benjamin Arubas and Shatil Emmanuilov)

unique architectural features from this early phase are the volute capitals (the so-called Proto-Aeolic capitals, a type of stone capital characteristic of palaces and public buildings in Israel and Judah), relief in the line of small stone columns, a series of small carved stone columns with tiny palmette capitals that had been part of a window balustrade (similar to those that appear in the reliefs known as “the woman in the window”), and pyramid-shaped stones (crenellations). All these items continued into the second building phase. There is no other site in Judah with so many one-of-a-kind and high-quality architectural items (Figs. 4 and 5).

Many small finds and a lot of pottery that was discovered in the fill beneath the second-phase floors should be also assigned to the first building phase. It includes about 70 jar handles with LMLK and “private” stamp impressions, representing all the known varieties dated from the late eighth to the mid-seventh centuries BCE. The unique architectural elements, the many stamp impressions, as well as the ceramic assemblage confirm that already in the early phase the site served as an

administrative and governmental center. Since Judah was under the rule of the Assyrian empire, it might be that Ramat Raḥel was the main center for collecting wine and oil jars, probably as a levy (Fig. 6).

To implement the comprehensive planning concept of **the second building phase**, dated to the second half or even the last quarter of the seventh century BCE, significant logistical and operational groundwork was required. A large quantity of material was extracted from the natural hill on its western side in order to create a garden sunk into the bedrock. All the quarrying waste was used as fill, removed, and poured over the eastern slope. This fill created a large level base upon which palace units and courtyards were constructed. As a result, the edifice was constructed in an east to west orientation despite its location on a hill that faced southeast–northwest. This indicates that this complex was built according to a predetermined architectural plan that intentionally disregarded the area’s topography. The tower fortress of the first phase was integrated into the new, enlarged plan. At the

Ramat Raḥel, Fig. 4 Architectural features from the Iron Age (Adapted by Ido Koch)

time of the construction of the sunken garden, the fortress was isolated on three sides – south, west, and north – and stood upon a prominent rock cube projecting westward out of the palace complex.

The garden extended around the western tower on its northern, western, and southern sides, on a lowered, leveled surface covering 1.5 acres (0.6 ha, 6 dunams) and possibly more. In creating the sunken garden, the planners removed the *nari* rock from the natural surface and created a leveled and unified rock surface. This surface was covered by a 17.7 in. (45 cm) deep layer of amalgamated brown garden soil, free of stones and sherds, that was artificially placed upon the leveled limestone surface. Other features incorporated into the flattened area related to water: at least three and possibly four plastered pools with three rock-cut and roofed tunnels, two exceptionally well-built drains, channels, gutters, and a large underground water reservoir (Fig. 7).

A rectangular palatial complex was constructed at the top of the mound, surrounded by casemate walls on its northern, eastern, and southern sides, with a 6,458.3 ft² (600 m²) inner courtyard in the center and an approximately 4,843.8 ft² (450 m²) outer courtyard to the east.

The palace of the second building phase was not destroyed in the late Iron Age and probably continued to function during the sixth century BCE. Hundreds of broken pottery vessels; ten restored jars, some of them bearing stamp impressions on jar handles of the early YHWD [YHWD is the Aramaic name of the province of Judah] types and some with sixth-century “private” stamp impressions, together with lion stamp impressions on body sherds, were unearthed in a huge pit to the south of the edifice. This assemblage stands as a clear marker for sixth-century BCE pottery, administration and economy, a clear indication for the existence of an unbroken economy and administration in Judah from the end of the seventh to the fifth and fourth centuries BCE.

The profusion of artifacts found at Ramat Raḥel shows a significant presence at the beginning of the Second Temple period – **the third building phase**. Of special importance are the 365 YHWD stamp impressions of the Persian and Hellenistic periods (out of a total of about 640 known to date), a clear indication that during the Persian and early Hellenistic periods the edifice at Ramat Raḥel was used in an administrative/governmental capacity for collecting wine and oil jars in Judah, probably as a levy. During this period, a large, sturdy building was added to the northwestern side of the second-phase palace complex covering an area of about 6,458.3 ft² (600 m², about 65.6 by 98.4 ft [20 by 30 m]). It probably served as a northward expansion of the fortress tower extending west of the line of the palace.

The garden that surrounded the palace continued to exist during the Persian period and went out of use in the third century BCE. Pollen research conducted at the site enabled a first attempt at answering the riddle of what flora had grown in the garden and the function it had served during the Persian period. According to the

Ramat Raḥel,**Fig. 5** Window balustrade and example of “the woman in the window” motif

pollen, besides the native Mediterranean maquis/forest taxa, fruit trees and ornamentals, which had certainly been planted specifically for aesthetic and symbolic reasons, were grown in the garden. The most surprising fossil pollen found was the citron (*etrog* in Hebrew, a word with a Persian precursor). This tree apparently arrived in the area from India via Persia and is the earliest botanical evidence of its presence in the southern Levant. Also, the Persian walnut originated in northern Iran, northeastern Turkey, and the Caucasus, and its Hebrew name, *éḡôz*, is also a word with a Persian precursor. Other imported trees identified in the pollen assemblages of Ramat Raḥel are cedar of Lebanon and birch. The pollen evidence of these exotic trees in the palatial garden suggests that they were brought by the ruling Persian authorities from remote parts of the empire as a royal extravagance.

The presence of local garden plants like myrtle, grapevine, and the common fig completes the

picture of the garden. Willow and poplar, which were also identified, are common to riverbank vegetation and therefore probably required irrigation; to these one can add the presence of pollen belonging to the water lily. All these flora species and their origins point to the fact that the garden was in bloom during the Persian period. Its imported trees from far-off lands, aromatic plants, and impressive fruit trees, together with its aesthetic architectural features, symbolized the power and affluence of the Persian-period rulers. It seems that with this combination of magnificent edifice and luxurious garden during the Persian period, Ramat Raḥel was not just an administrative center but served as the edifice of the imperial governor in the province, side by side with Jerusalem, which renewed its status as the lone cultic site, the location of the Temple, and the seat of the priests.

Following the end of the Persian period, Ramat Raḥel lost its prominence and some of

Ramat Raḥel, Fig. 6 Stamp impression types found at Ramat Raḥel (Illustration by Rodika Penchas)

the walls of its complex were robbed. Its status during the early Hellenistic period is cloaked in obscurity, but it seems to have regained its standing as an administrative center at the beginning of the second century BCE. This is mainly evidenced by the distribution of *yehud* and YRŠLM [Hebrew letters for Jerusalem] stamped handles. Remains of the citadel from this period were located on the eastern edge of the site, and it was probably a fortifying wall that was built upon the eastern wall of the former complex. The plan and exact location of this citadel are, however, not clear.

A drastic change in the history of Ramat Raḥel occurred during the late Hellenistic period, probably in the second half of the second century BCE, when the fortified edifice was completely obliterated. Its walls were robbed and the stones removed from the foundation trenches. The

thoroughness with which the stones were excised from the foundation channels, the furnaces constructed next to the water pool in the southern section of the garden, and the entire area covered over with fill suggest that it was an intentional act of annihilation carried out in order to eradicate the ancient garden and the buildings at the western front of the site. Demolishing the royal complex in this way was probably meant to obliterate from the landscape, and consequently the social memory, any reminder of the base that had for centuries served as the administrative center of imperial rule in Judea.

The character of the settlement that developed in the area during the late Hellenistic and the early Roman periods (late second–first centuries BCE and during the first century CE to the Great Revolt, 66 CE) can only be understood from its rock-cut installations since in most cases the walls of the buildings were dismantled or robbed for secondary use during the late Roman and Byzantine periods. Such installations include at least 13 ritual baths and two columbaria [a cave used to grow pigeons]. The pottery vessels and the many coins unearthed all over the site demonstrate that it became a Jewish settlement that existed up until the Great Revolt.

As a direct result of the suppression of the Judean rebellion and the destruction of Jerusalem, Ramat Raḥel, like other villages in the Jerusalem area, ceased to exist. The numismatic evidence clearly shows the lack of Judean coins later than year two of the rebellion. Furthermore, there is a very pronounced lack of evidence that can substantiate the existence of a settlement or any other Judean activity at the site during the period between the two Judean revolts.

Following the two revolts against the Romans the ethnicity of the Ramat Raḥel population changed. The site was abandoned for a short period and then reoccupied as a Roman village. A Roman country villa (of the kind known as *villa rustica*), equipped with a typical bathhouse, was built during the second half of the second century or in the early third century CE as part of a new settlement model that developed, at least in the area south of Jerusalem, and was based on an array of private estates. It seems reasonable to

Ramat Raḥel,

Fig. 7 Aerial view of the garden area (Photo by Sky-View)

assume that all these sites were the private estates of the high officials of provincial rule or Roman veterans who had close connections to the military units that were camped in the area.

From this period and up to the Umayyad period (eighth century CE), an organic development can be detected in various areas of local community life. Over a long period of time, no significant changes occurred in the nature of the settlement, yet it is still possible to track the physical expression of the changes that took place in accordance with the spatial–functional division. Thus, for example, in some cases, agricultural production facilities survived and continued to function, with some modifications, from the Roman period through the Umayyad period.

The process of Christianization of the Roman Empire had a profound effect on Ramat Raḥel, and this was expressed in the appearance of the church within the plan of the existing settlement. The church had already been uncovered in 1954, during Aharoni's salvage excavations in the northeastern sector of the site, together with a structure identified as a monastery on the other side of a stone alley. The church, it appeared, had been "planted" on the northeastern outskirts of the settled area, on top of earlier industrial

facilities and dwellings. It was a simple rural church, probably meant to serve the local population. The apse on the east was made of finely cut ashlar stones with remains of a fresco that was painted over the inner side. The pottery and coins unearthed from beneath the foundations confirm that the church was built during the sixth, possibly the seventh, century CE, much later than the Kathisma Church, just a few hundred meters southwest of the summit of the tell, on the third mile of the main road between Jerusalem and Bethlehem, just as the location of the Kathisma is described in the New Testament.

Rangoli: Versatile Domestic Art

Jyotsna Kamat

The art of rangoli (also known as alpana, saaz, muggu, kolam, zuti, mandana, and by many other names in India) is a traditional art of decorating courtyards and walls of Indian houses, places of worship and sometimes eating places as well. The powder of white stone, lime, rice flour, and other cheap paste is used to draw intricate and ritual designs. Each state of India has its own way of painting rangoli (Fig. 1).

Women's Art

One characteristic of rangoli is that commoners paint it, without much background in geometry, fine arts or mathematics. Women use their bare fingers or a homemade brush to create various designs from sandstone powder or grain flour. Sometimes colors and petals are used in addition to flour paste. Some women are so skilled with their fingers that they can create figures of deities, chariots, temples, etc., on the finely layered floor. Petals of various flowers, such as oleanders, cosmos, zinnia, chrysanthemums, and green leaves provide the artist with the ability to work out various patterns and colors. Most of the rangoli designs are motifs of plants, flowers, leaves such as coconut, lotus, mango, and ashwath (peepal), animals such as cows, elephants, and horses, and birds like eagles and swans. There are geometrical designs as well. When drawn with the fingers, these acquire different dimensions of their own (Fig. 2).

The rangoli art is practised as a ritual to welcome the goddess of prosperity, Lakshmi, into the home. Hence the first duty for housewives and young girls in the morning is to sweep the courtyard clean and draw rangoli patterns. Old and young alike participate in this ephemeral domestic art which changes every day.

Rangoli: Versatile Domestic Art, Fig. 1 Example of a Rangoli design (Illustration by K. L. Kamat)

We see that rangoli is predominantly a ritual performed by women. Men draw rangolis in temples and in public places.

History of Rangoli

The history of rangoli is quite ancient. Early rock paintings have symbols and figures of wild animals, hunting scenes, etc., to ward off evil and wish success in hunting expeditions. By the time of the Indus valley civilization (3000 BC), symbols like triangles, circles, and *swastikas* were used to represent supernatural powers. During the Vedic period, places to seat guests and sacrificial altars were decorated with floral designs. By the use of the hand and deft movement of the figures, rangoli has developed into a fine art over centuries. At times, a simple home-made brush is used (Fig. 3).

Complex Geometry and Philosophy for Common Folk

Almost all of the rangoli patterns involve dots (*bindu*) and lines (*rekha*); joining these creates innumerable patterns. A spot suggests power or life. A line suggests the flow of life. A circle represents the universe and a triangle signifies woman's power or fertility. The swastika stands

Rangoli: Versatile Domestic Art, Fig. 2 Rangoli to welcome God (Photograph by K. L. Kamat)

for the sun's movement. Some interpret that it represents fourfold achievements for householders as laid down by sacred texts. These are *dharma* (virtuous life), *artha* (earning livelihood), *kama* (creature comforts), and finally *moksha* (renunciation in old age). The four corners of the swastika are supposed to symbolize these ideals.

The sun, the moon, the stars, conches, and lotus are considered sacred figures in rangoli. Animals like elephants, cows, horses, tortoises, and birds like parrots, peacocks, and swans, along with plants and creepers, are often included in this art that combines geometry with philosophy and devotion with beauty.

Rangoli in Contemporary India

Festivals dedicated to different gods provide change in the daily routine of rangoli. During Naga panchami, symbols of serpents will appear.

Rangoli: Versatile Domestic Art,

Fig. 3 Women joining dots to make complex designs (Photograph by K. L. Kamat)

On Deepavali, the festival of lights, small earthen lamps will be drawn. On Sankranti festival day, sugarcane, paddy, and wheat sheaves, which are fresh at that time, will find a place of honor in the front door rangoli. Usually every Hindu house has a platform built round the sacred plant of Tulasi. On festival days, this place will also get a special design in addition to the daily ones. Patterns of flowers are popular. Innovative artists paint Christmas and New Year's greetings also in the form of rangolis, depicting Santa Claus and nativity scenes.

During Car festival, the entire village or townspeople will decorate the paths with colorful rangoli designs through which the deity's car (chariot or *ratha*) will pass.

With smaller flats in cities, this temporary and renewable art is disappearing. More and more households find it convenient to decorate their houses with permanent paints; however, they continue to use traditional rangoli designs.

Rationale in Indian Mathematics

K. V. Sarma
 Madras, Tamilnadu, India

Rationale in Hindu mathematics and astronomy is expressed by the terms *Yukti* and *Upapatti*, both meaning "the logical principles implied." It is characteristic of the Western scientific tradition, from the times of Euclid and Aristotle up to modern times, to enunciate and deduce using step-by-step reasoning. Such a practice is almost absent in the Indian tradition, even though the same background tasks of collecting and correlating data, identifying and analyzing methodologies, and arguing out possible answers have to be gone through before arriving at results. However, in the final depiction, only the resultant formulae would be given, and that too in short, crisp aphoristic form, leaving out details of all the background work. Commentaries generally content themselves with explaining the text of the formulae and adding examples. This tendency toward selective depiction of results has resulted not only in blacking out the background but also in not understanding the mental working of the

K. V. Sarma: deceased

Indian scientist. It also throws into oblivion the methodologies that had evolved. For this reason, many Indian advances have been branded as unoriginal and borrowed.

The situation is, however, relieved to some extent by the presence of a few commentaries which took pains to explain elaborately the methodologies adopted by the original author and also set out the rationales of the formulae he enunciated. Among such commentaries might be mentioned

- *Siddhāntadīpikā* on Govindasvāmī's *Mahābhāskarīya-Bhāṣya* by Parameśvara (1360–1465)
- *Āryabhaṭīya-Bhāṣya* by Nīlakaṇṭha Somayāji (b. 1444).
- *Yuktidīpikā* on Nīlakaṇṭha Somayāji's *Tantrasaṅgraha* by Śaṅkara Vāriyār (1500–1560)
- *Vāsanābhāṣya* on Bhāskarācārya's *Siddhāntaśiromaṇi* by Nṛsiṃha Daivajña (1621)
- *Marīcī*, again on Bhāskarācārya's *Siddhāntaśiromaṇi* by Munīśvara (1627)

A few texts devoted solely to the depiction of rationale are also known, such as the *Yuktibhāṣā* (Mathematical “Rationale in Language” Malayalam) by Jyeṣṭhadeva (1500–1610), *Jyotirmīmāṃsā* (Investigations on Astronomical Theories) by Nīlakaṇṭha Somayāji (b. 1444), *Rāśīgolasphuṭānīti* (True Longitude Computation on the Sphere of the Zodiac) by Acyuta Piṣāraṭi (1600), and *Karaṇapaddhati* (Methods of Astronomical Calculations) by Putumana Somayāji (1660–1740).

However, what is more significant is the occurrence of a number of short tracts giving mathematical and astronomical rationale which are available, some in print and several others in the form of manuscripts. These tracts take up individual topics of importance, analyze the technical principles involved therein, compare the procedures adopted in different texts, and often suggest revisions. To cite an example, the work *Gaṇitayuktayaḥ* (Rationales of Hindu Astronomy) contains a set of 27 tracts providing

rationalistic exegeses on several topics, including parallaxes of latitude and longitude, elevation of the moon's horns, constitution of epochs for new astronomical manuals, planetary deflections, and equation of the center. It is also noteworthy that some of these exegeses establish the originality of the methodologies and formulae depicted by Indian scientists.

Rationality, Objectivity, and Method

David Turnbull

Architecture Faculty, Victorian Eco-Innovation Lab (VEIL), Melbourne University, Melbourne, VIC, Australia

Rationality, objectivity, and method are three words that capture the essence of science and at the same time provide its mythic structure. Science has become the authoritative form of knowledge in the world today. The proof of its

superiority lies in the ever-expanding body of knowledge we have about reality. We can predict where, when, and how meteorites will collide with Jupiter, and we can build interplanetary spacecraft to send back signals recording the event. We can explore the atomic structure of chemicals and design new ones to suit whatever purpose we have in mind, ecstasy or health. We can map the human genome. We can explain the origins of everything in the universe down to the first few nanoseconds. The source, according to the myth, of this unparalleled success lies in science's embodiment of the highest form of rationality and objectivity in the scientific method. This mythical underpinning of science also provides the rationale for the celebration of modernity and the current domination of the West. This view is unselfconsciously exemplified by the philosopher Ernest Gellner who claims, "If a doctrine conflicts with the acceptance of the superiority of scientific-industrial societies over others, then it really is out" (cited in Salmond, 1985).

Therein lies the first set of intrinsic problems and contradictions the myth conceals. Modernity is supposedly synonymous with development and social improvement, but it has become apparent in recent times that science and technology are no longer unalloyed agents of progress. They now seem to contribute significantly to the difficulties we are facing in environmental degradation, pollution, climate change, and waste disposal. The other equally difficult emergent problem for the mythological account of science is that it has been seen as quintessentially Western and as absent in the developing countries or an undeveloped possibility in the Islamic, Chinese, and Indian cultures. This can no longer be accepted as a simple fact, but has now to be seen as an ideological marker in the creation of the "other." We have then a joint problem. On the one hand "the future is not what it used to be," courtesy of the negative effects of science and technology, but we will nonetheless have to call on them for their problem solving capacities. On the other hand it is becoming apparent that the grand project of modernity – a universal scientific culture – has failed and ought to be

relinquished in favor of encouraging cultural diversity. Just as biological diversity has become recognized as an ecological necessity so too has our cultural survival come to be seen as dependent on a diversity of knowledge (see knowledge systems). Consequently "the central problem of social and political theory today is to decide the nature of communicatory reason between irreducibly different cultures" (Davidson, 1994). Given this double difficulty we need to ask ourselves if science can be reconstituted.

Rationality

It is in trying to explicate rationality, objectivity, the scientific method and the nature of science that the myth of science's transcendental supremacy really comes undone. Rationality is a deeply problematic concept. It is profoundly embedded in the hidden assumptions of late twentieth century occidentalism about what it is to be a knowing, moral, sane individual. Indeed it is so embedded that to be anything other than rational is to be ignorant, immoral, insane, or a member of an undifferentiated herd. Hence rationality cannot be treated as simply an epistemological concept about the conditions under which one can know something; it also carries ideological overtones, privileging certain ways of knowing over others. Rationality is a constitutive element in the moral economy.

Yet despite, or perhaps because of, this central role of rationality, there are no fully articulated rules or criteria for being rational in the acceptance of beliefs or in the pursuit of knowledge, nor is there a single type of rationality. This sense of incoherence in the concept reaches total intransigence in the recognition that ultimately there can be no rational justification for being rational. Nonetheless critical rationalism as advocated by Karl Popper has a primal persuasiveness in contemporary Western society. Mario Bunge has captured some of that self-evidentiality and variability in his seven desiderata for rationality:

1. Conceptual: minimizing fuzziness, vagueness, or imprecision

2. Logical: striving for consistency, avoiding contradiction
3. Methodological: questioning, doubting, criticizing, demanding proof, or evidence
4. Epistemological: caring for empirical support and compatibility with bulk of accepted knowledge
5. Ontological: adopting a view consistent with science and technology
6. Valuational: striving for goals which are worthy and attainable
7. Practical: adopting means likely to attain the goals in view

Indeed seeing them set out like this makes their denial seem irrational.

From a relativist's perspective there are no universal criteria of rationality, and even if the claim for rationality's governing role is weakened to talk of desiderata as Bunge does, Wittgenstein's and Godel's point prevails: all formal systems are necessarily incomplete, no body of rules can contain the rules for their application. Rationality consists in the application of locally agreed criteria in particular context or as Foucault puts it, forms of rationalization are embedded in systems of practices (Foucault, 1979, p. 47). Hence it should be acknowledged that science, rather than exemplifying some transcendental rationality, has developed its own rationalities that have in turn served to create a great divide between science and traditional beliefs. There is of course a middle ground, the so-called bridgehead argument which calls for the recognition that all humans have some minimal forms of practical rationality in common. Though this recognition has produced no universal truths and no universal criteria, it nonetheless provides the grounds for a commonality sufficient for partial communication and understanding across linguistic, ontological, and cultural differences.

There is a philosophical tendency to talk of rationality as if it were a problem with no historical or sociological dimensions. This is to ignore the fact that the concept of the individual as a rational actor that is now so basic to Western ways of thought is not derived from first

principles; it arose in conjunction with the development of modern science in the seventeenth century. This was a period which saw great debates over the appropriate forms of rationality between the Cartesian rationalists and the Baconian empiricists. Whether true knowledge was to be derived deductively from self-evident first principles or by observation and experiment, it had already been accepted that the acquisition of such knowledge was within the capacity of human individuals. The recognition that human reason and experience was not inherently limited and could be a source of knowledge re-emerged in the twelfth and thirteenth centuries in the West with the separation of the church from the state and with the development of secular law from the accompanying canon law (Berman, 1983). The development of this conception of rationality was not universal. For example it was not paralleled in Islamic society where men were denied rational agency; they were held to lack the capacity to change nature or to understand it. Knowledge was instead to be derived from traditional authority. This is not to claim that there has been no Islamic science or any Islamic discussion of rationality (Huff, 1993). On the contrary, there have been major achievements in Islamic science but in a radically different moral economy.

While the notion of the rational actor as unconstrained by circumstance or authority and moved only by logic and evidence has become embedded in our legal, economic, and scientific presuppositions, such an idealized conception is at variance with our lived reality both at the societal and the individual level. At the societal level, modern Western capitalism has become a bureaucratic system that, as Weber pointed out, relies on a calculative rationality (Weber, 1979). The administration and perpetuation of this system is crucially dependent on a system of rules from which legal and administrative calculations can be derived by professional, objective, experts. Hence modern science and capitalism are interdependent; they were coproduced on the basis of a calculability derived in part from rational structures of law and administration. In Weber's view it is the specific and peculiar rationalism of western culture that makes science

unique to the west. Even if Weber was right, what needs further examination is how specific and peculiar that calculative rationalism is. That form of rationality has a number of interwoven components, for example the acceptance of written documents as evidence as opposed to oral testimony. This transition also occurred in the twelfth and thirteenth centuries but required the development of a “literate mentality” before it became self-evident that records and archives were more worthy of belief than the word of “twelve good men and true” (Street, 1984). Some, like Goody, have further argued that the accumulation of knowledge and the possibility of criticism and hence rationality are only possible in a literate culture. Similarly vision had to be rationalized to provide grammar or rules for the relationship between the representation of objects and their shapes as located in space. Yet another component of the form of rationality we equate with science was the acceptance of the validity of experimental evidence. Shapin and Schaffer have argued in *The Leviathan and the Air Pump* that Thomas Hobbes was able to dismiss Robert Boyle’s experiments on the vacuum as private, local, and artifactual until Boyle was able to introduce a range of social, literary, and technical practices that enabled the knowledge produced in the isolation of the laboratory to be “virtually witnessed” and reproduced for other audiences and in other laboratories (see Knowledge Systems).

Rationality is not a particular human capacity. Rather there are forms and compounds of rationality which at the societal level, as Foucault has shown, are dependent on particular social and historical institutions, constituted through the interwoven practices, techniques, strategies, and modes of calculation that traverse them. However, at the individual level we do not behave like the ends/means optimization calculators that economic rationalism would have us believe we are. We are at least as interested in meaning, significance, and personal values as we are in economic concerns. Nor are we quite the rational agents basing our knowledge on direct experience that the legal and philosophical theorists claim. A vast preponderance of our knowledge derives not from personal experience but

from books, newspapers, journals, teachers, and experts. In other words our knowledge comes, directly or indirectly, from the testimony of others, in particular from those we trust. Thus our individual lived rationality is based in a range of social practices, traditions, and moralities that are suppressed and concealed in the portrayal of rationality as an ahistorical, universalistic form of reasoning exemplified by science.

Objectivity

Much the same can be said of objectivity. Objective knowledge is held to be the product of science that has established methods to ensure that individual, institutional, and cultural biases are eliminated. On closer examination objectivity is not characteristic of one special kind of knowledge – science. Rather it is the result of whatever institutionalized practices serve in a particular culture to create self-evident validity. Objective knowledge, in modern terms, is held to contrast with subjective knowledge. It is knowledge that is not local, that is not contingent on the circumstance, authority, or the perspective of the individual knower. However, the concept of objectivity, like that of rationality, is not immutable; it is an historic compound. In the seventeenth century objectivity meant “the thing insofar as it is known.” The concept of aperspectival objectivity emerged in the moral and aesthetic philosophy of the late eighteenth century and spread to the natural sciences only in the mid-nineteenth century as result of the institutionalization of scientific life as a group rather than an individual activity.

This characterization of objectivity as the “view from nowhere” (Nagel, 1986) represents one of the essential contradictions of scientific knowledge production. Knowledge is necessarily a social product; it is the messy, contingent, and situated outcome of group activity. Yet in order to achieve credibility and authority in a culture that prefers the abstract over the concrete and that separates facts from values, knowledge has to be presented as unbiased and undistorted, as being without a place or a knower.

Objectivity, like democracy, is at best a worthy goal but one that is never capable of achievement. Since knowledge is the product of social processes it can never completely transcend the social. Objective knowledge cannot, for example, simply be knowledge which is unaffected by nonrational psychological forces, since scientists always have motivations even if they pursue knowledge for its own sake. Nor can objectivity be restricted to the avoidance of dogmatic commitment, because there have been scientists like Kepler whose obsession with regular solids and cosmic harmony led to his derivation of the laws of planetary motion. While it may be possible to avoid personal idiosyncrasy this can only be achieved through the establishment of communal or public knowledge. If knowledge is a communal product, then the question of how the community should be constituted arises. Should the scientific community be an essentially western institution? Consequently objective knowledge cannot simply be “value free” knowledge because what is counted as knowledge is itself a value. Similarly the criterion of practical effectiveness cannot determine objectivity since it too is based in community standards.

The only remaining possibilities for objective knowledge lie in the notions of correspondence with reality and experimental verification. There are well known difficulties here, since correspondent theories of truth and verification are dependent on empiricism and the scientific method, both of which have been subject to powerful criticism in the last half century or so. Essentially, what philosophers like Duhem, Quine, and Wittgenstein have argued is that our ways of knowing about the world are riddled with indeterminacies; which is to say that there is no set of procedures sufficiently powerful to determine which knowledge claims are absolutely true and certain, nor is there a certain way of grounding such claims. There are uncertainties inherent in all our ways of knowing that have to be bridged by a variety of practical and social strategies. Popper and Kuhn have argued that neither deduction nor induction is capable of providing true and certain knowledge. Furthermore observations and theories are interrelated and hence

neither can be an independent foundation for the other. Both Popper and Kuhn recognize that observations have point and meaning within the context or framework of a theory: we do not simply observe natural phenomena, we observe them in the light of some theory we already have in mind, or minimally with some set of expectations about what is interesting or what to look for. In this sense our observations of the world are “theory dependent” or “theory laden.”

As Duhem points out, all theories are enmeshed in a web of other theories and assumptions. The apparent conflict between an experimental result and a particular hypothesis cannot conclusively lead to the rejection of that hypothesis, since the strongest conclusion that can be drawn is that the hypothesis under test and the web of theories and assumptions in which it is embedded cannot both be true. Since the experimental result by itself is insufficient to tell us where the flaw lies, we can always maintain a theory in the light of an apparently falsifying experiment if we are prepared to make sufficiently radical adjustments in the web of our assumptions. Conversely it is the case that for any given set of facts there is an indeterminably large number of possible theories that could explain them.

In addition to the problematic relationship of theory and observation there is a difficulty concerning the language in which our claims about the world are expressed. All propositions or observation statements contain descriptive predicates which imply a classification or categorization of the world based on postulated essences or natural kinds. We are stuck with some degree of circularity since we gain our knowledge about natural kinds from theories which are in turn based on observations. There is no neutral observation language; our only option is to recognize and acknowledge the conventional character of our linguistic classifications.

Scientific Method

Despite all these difficulties scientists are able to reach firm conclusions about the natural world.

How is this possible? Many would claim that even though it may be logically true that there are an indefinite number of possible explanations for a given body of facts, in a given case there are typically a very restricted set of alternatives and there are adequate means of selecting the right theory, or at least the best possible theory in the circumstances, given the application of certain criteria. For example, we obviously desire theories which are internally coherent, consistent with other accepted theories, and simple rather than complex. However coherence, consistency, and simplicity as well as other criteria like plausibility have all proved notoriously difficult to express in a way which can be used to measure all theories in all circumstances. It is, none the less, very tempting from our twentieth century standpoint, imbued as we are with the scientific ethos, to suppose that there must be a particular set of rules, procedures, and criteria to which all scientists adhere. Taken together they should constitute the scientific method, and by diligent application of this method we should be able to arrive at all the scientific discoveries of our age. However, Paul Feyerabend in *Against Method*, for example, argues that no proposed set of rules and procedures has survived criticism or has been universally adopted by all scientists in all circumstances. Likewise he claims that in no case can it be shown that the success of science can be solely attributed to its adherence to the scientific method.

There can of course be endless debates about such claims, but so far no one has been able to identify the one scientific method which has been adopted in all the sciences. Compare for example theoretical physics (mainly mathematical) and biology (mainly observational). Nor is there a method which has been unilaterally accepted in a particular discipline. Compare again, Newton's espoused methodology ("I feign no hypotheses") with Einstein's (bold hypotheses and deductive tests). Further, particular instances of scientific practice under close examination reveal a pragmatic willingness to suspend or modify any particular version of the scientific method if necessary, as Feyerabend has shown in his analysis of Galileo and Copernicus. It seems then that

there is no "single, invariant methodology of science." Instead there are series of complex interactions between method and practice. As science and technology develop, so the practitioners develop and negotiate the rules for doing them in a local and contingent fashion. New methodologies are propounded in order to provide support and credibility to a newly preferred scientific theory.

Scientific Practice

It could be argued that the indeterminacies of science and the lack of a specific scientific method are merely philosophical and theoretical problems, and that science is firmly grounded in experimental practice. The best way to know whether a particular knowledge claim about the world is true or false is to subject it to experimental test and then have somebody else repeat the experiment.

There are two kinds of related difficulties with this empirical approach. Experiments are inevitably performed on a simplified, artifactual, and isolated portion of reality. Hence the universal generalizations drawn from them are not indubitable. Cartwright (1983) goes so far as to claim that the Laws of Physics are, in effect, lies. Equally the effectiveness of experimental replication as the litmus test of truth is somewhat undermined by the role of skill or tacit knowledge in scientific practice. "The problem being that, since experimentation is a matter of skillful practice, it can never be clear whether a second experiment has been done sufficiently well to count as a check on the results of the first. Some further test is needed to test the quality of the experiment – and so forth" (Collins, 1985). This result in what Collins calls "the experimenter's regress." In the normal course this is resolved by social processes in which the judgment about whether to accept a particular result is based on the relevant community's evaluation of the skills of the experimenter in question. It becomes deeply problematic when the existence of the phenomenon itself is at issue, as in the case of gravity waves. An experiment showing the

existence of such waves was followed by others seemingly denying their existence, or at least failing to detect them. Which was correct? The existence of gravity waves turns on the judgment of the community about competently performed experiments, and those judgments of competence are based on the accepted community knowledge about the nature of gravity waves. Replication then is not the test of their existence; rather it reflects the ability of the experimenter to achieve community standards of experimental practice.

Thus it would seem that conceptions of rationality, objectivity, and the scientific method cannot be derived from self-evident epistemological principles. They are instead embedded in the historically contingent processes of scientific practice, whereby the resistances and limitations of reality are encountered and accommodated. Science is a social activity that is essentially dependent on community and tradition, and the practice of science is governed by concrete, discrete, local traditions which resist rationalization.

The notion of a great divide between Western and so-called primitive knowledge systems has turned crucially on the question of rationality of science. If, as the arguments above suggest, science has a rationality of its own, but not one that is especially privileged, how do we both account for and deal with similarity and difference between cultures? How is it, on the one hand, that the peoples of the world are sufficiently alike to have universally developed complex languages, and yet those languages and their accompanying knowledge systems have produced profoundly different cultures? On the other hand, how are we to ensure communication and preserve cultural diversity?

In the entry on local knowledge it is claimed that the common element in all knowledge systems is their localness, and that their differences lie in the way that local knowledge is assembled through social strategies and technical devices for establishing equivalences and connections. It is no small reflexive irony that this entry on rationality and science and the encyclopaedia itself are dependent on unspoken assumptions concerning their credibility and authority which

constitute a form of rationality. The encyclopaedia is based on the assumption that widely disparate knowledge can be meaningfully assembled into a volume without loss of coherence due to incommensurability. Furthermore it is assumed that the individual articles, dependent as they are on evidence, analysis, and argument, are capable of being read, understood, and utilized by readers from all cultures. In other words there is a strong resemblance between this encyclopaedia and the practice of science. Science is dependent on the assemblage of heterogeneous inputs, but that assemblage is not achieved by the application of logical and rational rules or conformity to a method or plan. Indeed it is not even dependent on a clearly articulated consensus. Rather the assemblage results from the work of negotiation and judgment that each of the participants puts in to create the equivalences and connections that produce order and meaning. Perhaps then it has to be acknowledged that there is a minimal rationality assumption, and that links between rationalities can either be created or ignored by common human endeavor. So, given the lack of universal criteria of rationality the problem of working disparate knowledge systems together is one of creating a shared knowledge space in which on the one hand equivalences and connections between differing rationalities can be discursively constructed; and on the other hand where no common ground can be created, agreement can be sought to work with the creative tension of difference. A good example of such competing rationalities in tension is the irrigation system of Bali. Stephen Lansing's analysis shows the crucial role of the symbolic system of water temples in managing the flow of the waters, a role that classic Weberian forms of rationality have in the past simply dismissed as irrational (Lansing, 1991). Yet the role of the water temples was revealed by Lansing's anthropological and computer-based analysis. Communication, understanding, equality, and diversity will not be achieved by others adopting Western information, knowledge, science, and rationality, it will only come from negotiating ways to work together in joint and multiple rationalities.

Religion and Science in China

Wei Chen

Department of Mechanical Engineering,
Northwestern University, Evanston, IL, USA

“Religion and science in China” is a controversial topic which requires some clarification before the discussion can begin. Because the first serious efforts to bring Chinese classical study to the Western academic world were initiated by Jesuit missionaries in the seventeenth century, it became a Western tradition to look at many Chinese cultural phenomena from a religious point of view and categorize them accordingly. For a long time in the West, the three main *Jiao* (systems of teachings and beliefs) of Chinese traditions, Confucianism, Daoism (Taoism), and Buddhism, were called three religions. However, since the reconstruction of Chinese classical study early in this century, Chinese scholars generally consider Confucianism and Classical Daoism philosophies, popular Daoism a religion, and

Chinese Buddhism both a religion and a philosophy. Today in the West there is no consistent way of using these terms. All three are called either religions or philosophies or both, according to the idea or method or focus of the researcher. Furthermore, it is common practice to include other beliefs and activities in the study of religion, such as myths, rituals, customs, popular superstitions, and court divination rediscovered through mythological, linguistic, or archeological findings. These new studies are in fact turning the topic of “religion and science” into a much broader topic of “culture and science.”

On the other hand, the concept of “Chinese science” is even more uncertain. There is a strong tendency both in the West and in present-day China to question the possibility of a different kind of science. The underlying implication is the belief that there is only one science for one universe – The Science, which is objective and universal. With this belief in mind, explicitly or implicitly, historians of science generally consider Western modern science as the best approximation of The Science, and use it as a measure to search for relevant materials in Chinese ancient relics and texts. By using the same measure, Chinese ancient ideas, theories, studies of nature, and activities dealing with nature are accordingly classified into “scientific subjects” and thereby evaluated. The same belief also provides criteria for distinguishing nonscience from science. The danger of this viewpoint is that it will miss many of the real merits in cultures other than Western ones. One example is that the deep-set dichotomy of “body and soul (mind)” in the Western culture is typically a Greek tradition and may not be shared by other cultures. This difference will show itself especially in the different medical traditions.

For those who do not accept the idea of The Science, it becomes crucial to establish a reasonable or practical criterion for nonscience and science. Research efforts in this regard have not been successful either. Another confusion comes from the fact that in ancient China achievements in technology and in science are not easily distinguishable. There are doubts about if it makes sense or even if it is possible to define these two

concepts separately in the context of Chinese ancient culture.

With all these ambiguities in the main concepts and differences in the basic positions, the interaction between religion and [science in China](#) has not been formed into a regular study subject. In this article we will acknowledge that the concepts “religion” and “science” are both Western concepts used in a Chinese context. “Religion” means a system of beliefs and “science” means knowledge, especially theoretical or systematic knowledge about nature, human beings, and life, but not about human beliefs, activities, and relationships. Thus we will be able to achieve some clarity in our discussion.

The question of why the scientific revolution did not take place in China has drawn much attention during recent decades. A generally accepted conclusion is still far away, and may not even be important. In this article we will explore the influence exerted by the main Chinese ideologies on the nature and development of Chinese science. Here “main Chinese ideologies” means Confucianism and Daoism. Also, “Chinese science” means and includes Chinese ideas, theories, and knowledge about nature (including humans as natural beings) which were accepted by Chinese scholars or professionals in corresponding historical periods.

In the West in ancient times, science was under the strong influence of religions, and in modern times, religions were under the influence and pressure of the development of science. In China, science went along a different road; it started under the decisive influence of early Confucianism and philosophical Daoism. These two traditions governed the development of Chinese science. There were no serious conflicts between these governing ideologies and Chinese science until China began to bring in Western science on a large scale in the late nineteenth century. The conflict between Confucianism and Western science at that time has been a much studied topic.

After Buddhism was introduced into China around the first century, it gradually became the primary organized religion. However, little can be found in the development of Chinese science that was affected by the development of Chinese

Buddhism. One explanation of this phenomenon is that the characteristics of Chinese science, its subject matter and method, had been firmly established before the Qing dynasty (221–206 BCE). The nature of that science is quite compatible with the philosophy and practice of certain kinds of Indian Buddhism. On the other hand, together with Confucianism and Daoism, Chinese science might have exerted a strong influence upon the development of Chinese Buddhism, especially the Chan sect (the origin of the Japanese “Zen”). Little research has been done on this topic.

Our main concern will be the influence of ancient Confucianism and Daoism on Chinese science. We will begin with ancient cosmological beliefs and the methodology associated with these beliefs. As Confucianism and Daoism are the two schools that have been most influential in the making of Chinese culture, have preserved a great quantity of texts and historical records for their teachings, and have been thoroughly studied, the common features of these two schools will provide a good starting point in searching the origin of Chinese science. After this, we will also discuss how the difference between these two schools influenced the development of Chinese science in their own way.

Chinese Ancient Cosmological Beliefs

It is important to examine the basic concepts that were used in both Confucian and Daoist texts. Those that concern Chinese science are the concepts of Heaven, Earth, Human, *Dao*, *Te*, and Fate. Though Chinese classics do not provide definitions for these concepts, we can study the way they were used in their textual contexts and interpret their meaning approximately by using Western concepts as follows: Heaven and Earth form the natural world that Human lives in. Heaven is the part that is farther away from Human but is more fundamental in the sense that it ultimately governs and decides everything that happens to Earth and Human. Earth is the part of the natural world that surrounds and interacts

with Human directly. Human is the concept for every human being, who has a life that has a beginning, a growing process, and an end. The distinction between Heaven and Earth is of great importance in the interactive mechanism between Human and Nature. Human can act directly on Earth and change it and use it for his own purposes, but not on Heaven. Earth is governed by Heaven and not by Human; therefore, the way Human deals with Earth (e.g., agriculture and irrigation) can either be right or wrong according to whether it follows or violates Heaven’s way. This sounds quite like the Western idea of natural law and it seems compatible with modern scientific views, but there is a crucial difference. The Chinese “Heaven’s way”, which is called *Dao*, governs not only Earth, but also Human’s life and society, and therefore it is a moral matter whether one follows or violates it. To follow the *Dao* is not only a matter of what to do to achieve a certain purpose, like what science tells us in the West, but also what purposes one should have in all his/her activities including governmental, social, familial, and individual activities. Thus, *Dao* as the most fundamental principle or cosmological law is objective and natural, and governs the whole world which in Western categories splits into the natural world, society, and individual life.

To know *Dao* and therefore to act according to *Dao* is the goal of ancient Chinese study. The result of this study is to gain *Te*. *Te* is both knowledge in the sense of knowing what is right, and virtue in the sense of practicing what is right. Like knowledge and virtue in the West, *Te* can be both innate and acquired. That is, people are born with *Te*, to a greater or less degree, and can acquire and accumulate *Te* through study and practice in their lives. However, unlike the Western concepts of knowledge and virtue, *Te* can neither be defined by a general relationship, either functional or quantitative, nor be abstracted or theorized from its special context – the human conditions which define the reality of the individuals concerned.

The reality of an individual is his/her Fate, which is basically determined by Heaven.

That means it is out of human reach to change or control it. On the contrary, Fate is the realization of *Dao* in each individual's life. It can be known either through study and practice, or by divination. Ancient Chinese divination, like a certain kind of Greek oracle, does not tell what will happen in the future but answers if actions are right or wrong according to Heaven's way. Therefore, the concept of "good fortune" is not defined by positive results to individual purposes, nor satisfaction of natural or whimsical human desires, but by the realization of the *Dao*. Therefore, ancient Chinese divination, typically represented by the Yijing (I Ching, Book of Changes), has a close relation with the ancient Chinese value system and moral principles as well as understandings of *Dao*, and thus exerts great influence on the development of Chinese science.

Now when we look back at these beliefs, the following conclusions are apparent:

1. Because of the wide variety of its governed phenomena, and because of its moral nature, *Dao* is not a deterministic regularity which decides in every detail what happens in the world. Maybe it is, on the whole and in the long run, but certainly not in the form of an instant causal relationship in everyday phenomena which are available for measurement and observance. *Dao* is not a natural law which is impossible to violate.
2. If *Dao* is ultimately deterministic, it can be seen in history. Therefore, to keep historical records is tremendously meaningful and important for the Chinese, and to study these records, what is called historiography in Western terminology, is especially so.
3. If *Dao* is indeterministic in details, and can be violated by people for their wrong purposes, then it makes no sense to study *Dao* by mechanical experimenting, nor by searching underlying regularities in the observable movements of stars in heaven and things on earth. In other words, one cannot study *Dao* through instant causal relationships, because in these relationships there are no observables
4. Chinese divination has a nature of empirical knowledge which comes from generalization of phenomenological and historical observations, and a nature of theoretical knowledge which employs mathematical representation to calculate functional relations in the change of affairs. Not only does it exert great influence on the later development of Chinese science in its conceptual system and methodology, but also it could be looked upon as the earliest achievement of Chinese science.

Confucianism

Confucianism is the English word for *Ru Jia* (the School of Scholars), which was founded by Confucius (551–479 BCE), the first private teacher in China. Confucius is the Latinized form of *Kong Fuzi*, a respectful way of addressing the master. *Kong* was his family name. He lived in a time when the empire was being broken up into numerous feudal states. It was a time of change, disorder, and degeneration of the old moralities. When he started as an officer and political reformer, Confucius' ideas of personal cultivation and moral government failed to attract the rulers of his time. So he turned to teaching and taught a large number of private students, preparing them to be good court ministers as well as good teachers. Thus, he managed to exert an influence by establishing a tradition of individual learning and private education. In the second century BCE his ideas and teachings were made authoritative by the Han emperors, and the Classics Confucius edited and used in teaching became the only official textbooks in China until the beginning of the twentieth century.

Confucianism is *the* Chinese ideology. From the second century BCE to the beginning of the twentieth century, it has been the orthodoxy. In a way, it is the Chinese religion, because it provides a system of beliefs (or disbeliefs) and values which calls for faith and acceptance from

students, and also because it is more a way of life for students to follow than a body of knowledge for them to master. There are always scholars who spend their lives studying the text of Confucian Classics, but it is not through these studies that Confucianism exerts its influence on Chinese society and culture. In this regard, Confucianism is more comparable to Western religions than philosophies.

However, Confucianism is not a religion in the Western sense, because it has neither doctrine nor reference to the supernatural. It gives no promise, no reward, and no consolation to its followers either in or beyond this life. It has no God, no church, and no organization. It is only a teaching. It teaches the follower how to be a noble man (a *Junzi*) living a noble life in his special social context.

The ultimate goal of Confucius' teaching, and therefore the goal of Confucian learning, is the benefit of the people. The essence of Confucianism lies in these two doctrines (1) a moral government, i.e., governing by moral examples and education instead of by rules, law, and punishment, is the solution to social disorder and is to the highest benefit of the people; and (2) the cultivation of a group of *Junzi* (noble men) in a society is a practical road toward moral government.

A *Junzi* is an elite scholar. He is elite because he has higher moral standards and is therefore a better person than a common man (*Xiaoren*, the small men); but he is not an elite in the Western sense, because his higher moral standards require that he has no social privileges but only duties and obligations. To be a *Junzi* is both to lead a noble life and to have a noble personality; it is a lifelong task of self-cultivation without personal gains. One will choose to be a *Junzi* because he knows it is his fate.

To be a *Junzi* is the immediate goal for a Confucian. Because Confucians believe that people's benefit will be served best by bettering the government, people are left alone to deal with their own material needs, their production, and their struggle with the natural surroundings. Confucians take it for granted that common people are

naturally wise enough to deal with all that and take care of their own needs, and it is not *Junzi's* task to learn and develop knowledge and ability in this regard. Confucians believe that a moral society would naturally become prosperous.

The *Analects*, a basic Confucian classic, recorded that Confucius once refused to teach his student agricultural knowledge, saying the elder farmers and gardeners were better than he in this regard. This shows that *Junzi's* learning should be limited to the scope of human relationships, and science or scientific knowledge has no value to *Junzi's* task of self-cultivation.

This Confucian attitude toward scientific knowledge has its roots in the belief that the world Human lives in is governed by the *Dao*, and the best thing Human can do is to follow the *Dao*. In Chinese cosmology it is a Human choice, therefore a moral matter, to follow or to go against the *Dao*. Therefore, the Western task of changing the world according to man's ideas, or reforming the world to suit man's needs, would sound absurd and dangerous to the ancient Chinese, for it advocates going against the *Dao*. Human is a part of the universe, and not the governing part. Man is not the lord of the earth and cannot give orders to Nature. This is not to say that ancient Chinese did not make efforts to better their living conditions, but it does mean that they did not give these efforts high priority on the scale of social urgencies.

After Confucianism was made authoritative by Chinese emperors in the second century BCE nearly all Chinese intellectuals became Confucians, who formed an elite class in Chinese society. Generally speaking, Confucians looked down on technical and scientific knowledge and achievements because these neither had any use in self-cultivation, nor helped in turning the government into a moral one. This attitude left the development and preservation of scientific knowledge in the hands of professionals, many of whom were illiterate and kept their skills and knowledge as a family tradition. With the exception of astronomy, mathematics, and medicine, Chinese ancient technological and scientific achievements were seldom recorded or their

records preserved. When the British scientist and historian of science Joseph Needham started to search extensively through the extant texts for these records, and began to publish the results of his search in the multivolumed *Science & Civilization in China* (1954-), it shocked the world to see that Chinese themselves did not remember what they had achieved. Certainly the ancient Confucians would not value these “achievements” as much as modern Westerners do.

There is no doubt that this Confucian devaluation of scientific activity, knowledge, and achievements has been a significant hindrance to the development of Chinese science. However, Confucians did value the study of astronomy, mathematics, and medicine, though the former two were not necessarily as urgently needed by the people as the knowledge for agricultural production. The reason Confucians accepted them as a proper scholarly study is for their use in divination. Confucianism included divination in the basic teaching of *Li* (rites). Astronomy and mathematics were needed in making calendars, which were important for the agricultural economy. Medicine was an early tradition and developed into such a complicated system that it became an intellectual profession even before Confucianism gained its orthodox position.

Confucianism did allow for scientific and technological knowledge to grow among the professionals. The Confucian attitude toward science is to leave it alone. Science and technology are not Confucians’ proper concerns, but they never go against them. Under the reign of Confucianism there were no known cases in which scientists and innovators were persecuted because of their ideas or inventions. Confucianism created unfavorable social attitudes and conditions for scientific and technological development in China, only because Chinese rulers made Confucianism orthodox and turned the intelligentsia into Confucians. But we cannot oversimplify this situation and accuse Confucianism of smothering a scientific revolution which would otherwise have happened in China. When we study the three branches of science Confucianism valued, and compare them to Western

ones, it can be seen that they are metaphysically and methodologically different. What Confucianism did to Chinese science was external and only confined to social factors.

Daoism

The term Daoism in English has several meanings. In its basic meaning it is a translation of the Chinese *Dao Jia* (the School of *Dao*), which was represented by two Daoist classics: the *Lao Zi* and the *Zhang Zi*. In this sense, Daoism (also called Classical Daoism or Daoist philosophy) is an ancient philosophical tradition. In its second meaning Daoism is a translation of the Chinese *Dao Jiao* (the religion of *Dao*, or Popular Daoism). It includes a variety of later organizational developments of the Daoist religion, mostly imitating the form of imported Buddhism but incorporating the ideas of the *Lao Zi* and *Zhang Zi*. It was often involved in political issues, sometimes was used to organize and mobilize peasants’ uprisings, occasionally was used to seek favors from the court, and was thereby supported by Chinese emperors. It was a folk religion and Confucians looked down on it as low culture and superstition. In its third and very broad meaning, it is a vague concept that includes Classical Daoism, Popular Daoism, and some other schools that were similar to Classical Daoism. These other schools include the School of [Yinyang](#) and the School of *Huang-Lao* (the School of the Yellow Emperor and *Laozi*). It is in this last sense that we are now using the term Daoism.

Generally speaking Daoists emphasize individual happiness rather than social welfare. They believe in *Dao*, in cutting down one’s desires and wants, in living a simple, secluded, and natural life, and in cultivating spiritual as well as physical immortality. In the last aspect it is mysticism from a modern scientific point of view, but the method it uses in seeking the way of immortality, which according to Daoism should be realized in this life on earth, is very much empirical and congenial with the Western development of geography, health care, and elixir

alchemy. Thus, the influence of Daoism on the development of Chinese science is substantial.

The central idea that exerts a strong impact on the development of Chinese science is the search for immortality in this life on earth. We do not know what the origin of this idea is and when its practice started. There are three approaches: the first is by cultivating one's *Qi*, the second by making special drugs such as the elixir of life, and the third by going deep into mountains or on the seas to find living immortals to learn from. The concept of *Qi* is one of the most ancient Chinese concepts about nature and life. It was used, in the sense of vitality, in the works of the warring-states philosophers, such as Mencius, Xun Zi, Zhuang Zi, and Lüshi Chunqiu in the fourth and the third centuries BCE. The earliest extant text that mentioned elixir drugs is *Hanfei Zi*, which was in the third century BCE. *Shi Ji* (Records of the Historian, compiled during the second and the first century BCE) recorded that in the fourth and third century BCE the rulers of Chu and Yan states sent envoys sailing to learn about the ways of immortality.

These three approaches led to three developments of Chinese science. The first is Chinese medicine, including health care techniques and Qigong. *Qigong* is an Eastern exercise which is based on the theory of interaction between body and spirit and the possibility of controlling one's mental state by manipulating one's body. The second is somewhat connected with the development of Chinese pharmacology, but more so with that of chemistry which led to the invention of ► [gunpowder](#). The third helped to preserve ancient myths and legends, and initiated the need to exploit the outside world which Confucians neglected. The earliest Chinese geographical work, *Shan Hai Jing*, is basically the result of this effort.

The Daoist influence on Chinese science is more congenial with the criteria of modern science. Daoists believe in the power of true knowledge for their own purpose of immortality and that knowledge can be sought by experimenting or by learning from those who know. They accept that the truthfulness of that knowledge should be tested by the results of its applications. With their

beliefs of *Yinyang* and Wuxing (Five Phases), which are not religious but ontological and methodological, Daoism is the Chinese system of belief that led to the flourishing of Chinese medical theory and health care practices, which might be considered the highest achievements of Chinese science.

Religion and Science in Islam I: Technical and Practical Aspects

David A. King

Frankfurt University, Frankfurt am Main, Germany

In Islam, as in no other religion in human history, the performance of various aspects of religious ritual has been assisted by scientific procedures. The organization of the lunar calendar, the regulation of the astronomically defined times of prayer, and the determination of the sacred direction toward the Ka'ba in Mecca are topics of traditional Islamic science still of concern to Muslims today, and each has a history going back close to 1,400 years. But the techniques advocated by the scientists of medieval Islam on the one hand and by the scholars of religious law on the other were quite different, and our present knowledge of them is based mainly on research conducted during the past 30 years on one small fraction of the vast literary heritage of the Muslim peoples. To understand Muslim activity in this domain we must realize that there were two main traditions of astronomy in the Islamic Near East, folk astronomy and mathematical astronomy.

The Regulation of the Lunar Calendar

The Islamic calendar is strictly lunar. The beginnings and ends of the lunar months, in particular of the holy month of Ramadan, and various festivals throughout the 12-month "year," are regulated by the first appearance of the lunar crescent. Since 12 lunar months add up to about 354 days, the 12-month cycles of the Islamic calendar begin some 11 days earlier each year, and the individual months move forward through the seasons.

For scholars of the sacred law, the month began with the first sighting of the crescent moon. This observation is a relatively simple affair, provided that one knows roughly where and when to look and the western sky is clear. Witnesses with exceptional eyesight were sent to locations that offered a clear view of the western horizon, and their sighting of the crescent determined the beginning of the month; otherwise they would repeat the process the next day. If the sky was cloudy, the calendar would be regulated by assuming a fixed number of days for the month just completed. Also, the crescent might be seen in one locality and not in another. Unfortunately the historical sources contain very little information on the actual practice of regulating the calendar.

Medieval astronomers, on the other hand, knew that the determination of the possibility of sighting on a given day was a complicated mathematical problem, involving knowledge of the positions of the sun and moon relative to each other and to the local horizon. The crescent will be seen after sunset on a given evening at the beginning of a lunar month if it is far enough away from the sun, and if it is high enough above the horizon not to be overpowered by the background sky glow. Conditions required to assure crescent visibility on most occasions can be determined by observations, but the formulation of a definitive set of conditions has defied even modern astronomers. The positions of the sun and moon must be investigated to see whether the assumed visibility conditions are satisfied, but, even if they are, the most ardent astronomer can be denied the excitement of sighting the crescent at the predicted time if clouds or haze on the western horizon restrict his view.

The earliest Muslim astronomers adopted a lunar visibility condition which they found in Indian sources. It was necessary to calculate the positions of the sun and moon from tables and then to calculate the difference in setting times over the local horizon. If the latter was 48 min or more, the crescent would be seen; if it was less, the crescent would not be seen. In the early ninth century the astronomer ► [al-Khwārizmī](#) compiled a table showing the minimum distances

between the sun and moon (measured on the ecliptic) to ensure crescent visibility throughout the year, based on this condition and computed specifically for the latitude of Baghdad. During the following centuries Muslim astronomers not only derived far more complicated conditions for visibility determinations but also compiled highly sophisticated tables to facilitate their computations. Some of the leading Muslim astronomers proposed conditions involving three different quantities, such as the apparent angular separation of the sun and moon, the difference in their setting times over the local horizon, and the apparent lunar velocity. Annual ephemerides or almanacs gave information about the possibility of sighting at the beginning of each month.

The Regulation of the Five Daily Prayers

The times of the five daily prayers in Islam are defined in terms of astronomical phenomena dependent upon the position of the sun in the sky. More specifically, the times of daylight prayers are defined in terms of shadows, and those of night prayers in terms of twilight phenomena. They therefore vary with terrestrial latitude, and unless measured with respect to a local meridian, also with terrestrial longitude.

Because the months begin when the new moon is seen for the first time shortly after sunset, the Islamic day is considered to begin at sunset. Each of the five prayers may be performed during a specified interval of time, and the earlier during the interval the prayer is performed, the better. The day begins with the *maghrib* or sunset prayer. The second prayer is the *ishā'* or evening prayer, which begins at nightfall. The third is the *fajr* or dawn prayer, which begins at daybreak. The fourth is the *Zuhr* or noon prayer, which begins shortly after astronomical midday when the sun has crossed the meridian. The fifth is the *ʿaṣr* or afternoon prayer, which begins when the shadow of any object has increased beyond its midday minimum by an amount equal to the length of the object casting the shadow. In some medieval circles, the *Zuhr* prayer began when the

shadow increase was one-quarter of the length of the object, and the *ʿaṣr* prayer continued until the shadow increase was twice the length of the object.

In the first few decades of Islam, the times of prayer were regulated by observation of shadow lengths by day and of twilight phenomena in the evening and early morning. Precisely how either the daylight or the nighttime prayers were regulated is unfortunately not clear from the available historical sources. Muezzins who performed the call to prayer from the minarets of mosques were chosen for their piety and the excellence of their voices, but their technical knowledge was limited.

On the other hand, the determination of the precise moments (expressed in hours and minutes, local time) when the prayers should begin, according to the standard definitions, required complicated mathematical procedures in spherical astronomy, that is, the study of problems associated with the apparent daily rotation of the celestial sphere. Accurate as well as approximate formulae for reckoning time of day or night from solar or stellar altitudes were available to Muslim scholars from Indian sources and these were improved and simplified by Muslim astronomers. Certain individual astronomers from the ninth century onward applied themselves to the calculation of tables for facilitating the determination of the prayer times. The earliest known prayer-tables were prepared in the ninth century by ► [al-Khwārizmī](#) for the latitude of Baghdad. The first tables for finding the time of day from the solar altitude or the time of night from the altitudes of certain prominent fixed stars appeared in Baghdad in the ninth and tenth centuries. The extent to which these tables deriving from mathematical procedures were used before the thirteenth century is unknown. The earliest examples are contained in technical works which must have had fairly limited circulation; the muezzins certainly had no need of them. Only a professional astronomer could use the tables, together with some kind of observational instrument for measuring the sun's altitude and reckoning the passage of time.

It was not until the thirteenth century that the institution of the *muwaqqit* appeared in mosques and madrasas. These professional astronomers associated with a religious institution not only regulated the prayer times, but constructed instruments, wrote treatises on spherical astronomy, and gave instruction to students. In thirteenth-century Cairo, new tables were available, and these set the tone for astronomical timekeeping all over the Islamic world in the centuries that followed. In medieval Cairo there was a corpus of some 200 pages of tables available for timekeeping by the sun and for regulating the times of prayer; in numerous copies the tables are associated with Ibn Yūnus.

Impressive innovations in astronomical timekeeping were made in other medieval cities, especially Damascus, Tunis, and Taiz, although by the sixteenth century Istanbul had become the main center of this activity. Highly sophisticated tables of special trigonometric functions were compiled to solve problems of spherical astronomy for any latitude. Tables for finding the time of day from the solar altitude at any time of year were compiled for Cairo, as we have mentioned, and also for Damascus, Tunis, Taiz, Jerusalem, Maragha, Mecca, Edirne, and Istanbul. Medieval tables for regulating the times of prayer have been found for a series of localities between Fez in Morocco and Yarkand in China. Such tables have a history spanning the millennium from the ninth century to the nineteenth.

Astronomical tables for regulating the prayer times had to be used together with instruments; only in this way could one ascertain that the time advocated in the table had actually arrived. The most popular of these instruments were the astrolabe and the quadrant. Hundreds of Islamic astrolabes and several dozen quadrants are preserved in the museums of the world, only a small fraction of the instruments actually made by Muslim astronomers. An alternative means of regulating the daytime prayers was available to the Muslims in the form of the sundial. Many mosque sundials from the later period of Islamic astronomy survive to this day, though most are now nonfunctional.

The Determination of the Sacred Direction

The Ka 'ba in Mecca was adopted as the focal point of the new religion since the *Qur'ān* advocates prayer toward it. For Muslims it is a physical pointer to the presence of God. Thus since the early seventh century Muslims have faced the Sacred Ka 'ba in Mecca during their prayers. Mosques are built with the prayer-wall facing the Ka 'ba, the direction being indicated by a *mihrāb* or prayer-niche. In addition, certain ritual acts such as reciting the *Qur'ān*, announcing the call to prayer, and slaughtering animals for food, are to be performed facing the Ka 'ba. Also Muslim graves and tombs were laid out so that the body would lie on its side and face the Ka 'ba. (Modern burial practice is slightly different but still Mecca-oriented). Thus the direction of the Ka 'ba – called *qibla* in Arabic and all other languages of the Islamic commonwealth – is of prime importance in the life of every Muslim.

During the first two centuries of Islam, when mosques were being built from Andalusia to Central Asia, the Muslims had no truly scientific means of finding the qibla. Clearly they knew roughly the direction they had taken to reach wherever they were, and the direction of the road on which pilgrims left for Mecca could be, and, in some cases, actually was used as a qibla. But they also followed two basic procedures, observing tradition and developing a simple expedient. In the first case, some authorities observed that the Prophet Muḥammad when he was in Medina (north of Mecca) had prayed due south, and they advocated the general adoption of this direction for the qibla. This explains why many early mosques from Andalusia to Central Asia face south. Other authorities said that the Quranic verse quoted above meant standing precisely so that one faced the Ka 'ba. Now the Muslims of Meccan origin knew that when they were standing in front of the walls or corners of the Ka 'ba they were facing directions specifically associated with the risings and settings of the sun and certain fixed stars. They knew that the major axis of the rectangular base of the edifice points

toward the rising point of Canopus, and the minor axis points toward summer sunrise and winter sunset. These assertions about the Ka 'ba's astronomical alignments, found in newly discovered medieval sources, have been confirmed by modern measurements.

In addition Arabic folklore associates the sides of the Ka 'ba with the winds and rain. These features and associations cast new light on the origin of the edifice, and in a sense confirm the Muslim legend that the Ka 'ba was built in the style of a celestial counterpart called *al-bayt al-ma' mūr*: indeed it seems to have been an architectural model of a pre-Islamic Arab cosmology in which astronomical and meteorological phenomena are represented. The religious association was achieved first by a number of statues of the gods of the pagan Arabs which were housed inside it. With the advent of Islam, these were removed, and the edifice has for close to 1,400 years served for Muslims as a physical focus of their worship.

The corners of the Ka 'ba were associated even in pre-Islamic times with the four main regions of the surrounding world: Syria, Iraq, the Yemen, and "the West." Some Muslim authorities said that to face the Ka 'ba from Iraq, for example, one should stand in the same direction as if one were standing right in front of the north eastern wall of the Ka 'ba. Thus the first Muslims in Iraq built their mosques with the prayer-walls toward winter sunset because they wanted the mosques to face the north eastern wall of the Ka 'ba. Likewise the first mosques in Egypt were built with their prayer-walls facing winter sunrise so that the prayer-wall was "parallel" to the north western wall of the Ka 'ba. Inevitably there were differences of opinion, and different directions were favored by particular groups. Indeed, in each major region of the Islamic world, there was a whole palette of directions used for the qibla. Only rarely do the orientations of medieval mosques correspond to the qiblas derived by computation. Recently some medieval texts have been identified which deal with the problem of the qibla in Andalusia, the Maghrib, Egypt, Iraq and Iran,

and Central Asia. Their study has done much to clarify the orientation of mosques in these areas. In order that prayer in any reasonable direction be considered valid, some legal texts assert that while facing the *actual* direction of the Ka 'ba (' *ayn*) is optimal, facing the *general* direction of the Ka 'ba (*jiha*) is also legally acceptable.

In various texts on folk astronomy, popular encyclopedias, and legal treatises, we find the notion of the world divided into sectors about the Ka 'ba, with the qibla in each sector having an astronomically defined direction. Some 20 different schemes have been discovered recently in the manuscript sources, attesting to a sophisticated tradition of sacred geography in Islam.

The earliest schemes of Islamic sacred geography date from the ninth century, but the main contributor to its development was a Yemeni legal scholar named Ibn Surāqa, who studied in Basra about the year 1000. Ibn Surāqa devised three different schemes of sacred geography, with the world arranged in 8, 11, and 12 sectors around the Ka 'ba. Each sector of the world faces a particular section of the perimeter of the Ka 'ba. Simpler versions of his 12-sector scheme occur in such popular geographical works as the *Taqwīm al-buldān* of Yāqūt al-Rūmī (ca. 1200) and the *Āthār al-bilād* of al-Qazwīnī (ca. 1250) as well as the encyclopedia *Ṣubḥ al-a' shā* of al-Qalqashandī (ca. 1400). From the fifteenth century to the nineteenth, we find a proliferation of schemes with different numbers of divisions between 8 and 72 divisions of the world around the Ka 'ba.

Muslim astronomers from the eighth century onward concerned themselves with the determination of the qibla as a problem of mathematical geography. This activity involved the measurement of geographical coordinates and the computation of the direction of one locality from another by procedures of geometry or trigonometry. The qibla at any locality was defined as the direction of Mecca along the great-circle on the terrestrial sphere.

Muslims inherited the Greek tradition of mathematical geography, together with Ptolemy's lists of localities and their latitudes

and longitudes. By the early ninth century observations were conducted in order to measure the coordinates of Mecca and Baghdad as accurately as possible, with the express intention of computing the qibla at Baghdad. Indeed, the need to determine the qibla in different localities inspired much of the most sophisticated activity of the Muslim geographers (see below).

Once the geographical data are available, a mathematical procedure is necessary to determine the qibla. The earliest Muslim astronomers who considered this problem developed a series of approximate solutions, all adequate for most practical purposes, but in the early ninth century, if not before, an accurate solution by solid trigonometry was formulated. The accurate formulae derived by the Muslim astronomers from the ninth century onward are impressive, and are mathematically equivalent to the modern formula. Muslim astronomers also compiled a series of tables displaying the qibla for each degree of latitude and longitude difference from Mecca, based on both approximate and exact formulae, the first of these being prepared in Baghdad in the ninth century.

Over the centuries, numerous Muslim scientists discussed the qibla problem, presenting solutions by spherical trigonometry, or reducing the three-dimensional situation to two dimensions and solving it by geometry or plane trigonometry. They also formulated solutions using calculating devices. But one of the finest medieval mathematical solutions to the qibla problem was reached in fourteenth-century Damascus: a table by al-Khalīlī displays the qibla for each degree of latitude from 10 to 56° and each degree of longitude from 1 to 60° east or west of Mecca, with entries correctly computed according to the accurate formula. This splendid table (rediscovered only in the early 1970s) was not widely known in later Muslim scientific circles. *Muwaqqits* of later centuries wrote treatises about the determination of the qibla but did not mention this Syrian table. By the fourteenth century the correct values of the qibla of each major city had long been established (correct, that is, for the medieval coordinates used in the calculations). Simple

qibla-indicators fitted with a magnetic compass and a gazetteer of localities and qiblas became common, and the modern variety represents a continuation of this tradition.

Some of the most important Muslim contributions to mathematical geography are to be found in a series of treatises by the early eleventh-century scientist ► [al-Bīrūnī](#). In one treatise he set out to determine for his patron the qibla at Ghazna (in what is now Afghanistan), first establishing the necessary geographical coordinates and then calculating the qibla by different procedures. Since 1989 three Persian qibla-indicators, made in Isfahan about 1675, have become available for study. They bear a cartographic grid so devised that one can read the direction and distance to Mecca directly. Mecca is at the center of the grid and one has only to lay the diametrical rule over any city marked on the map (between Spain and China, Europe and the Yemen) to read off the qibla on a circular scale around the grid and the distance on the diametrical rule. The origin of this remarkable device is still under investigation; but the underlying mathematics is described in two treatises on conic sections, one from tenth-century Baghdad and the other from eleventh-century Isfahan. The tradition behind the Isfahan world maps represents the most sophisticated contribution to mathematical geography known between Antiquity and the Renaissance.

The alignment of medieval mosques reflects the fact that the astronomers were not always consulted on their orientation. But now that we know from textual sources which directions were used as a qibla in each major locality, we cannot only better understand the mosque orientations but also recognize numerous cities in the Islamic world that can be said to be qibla-oriented. In some, such as Taza in Morocco and Khiva in Central Asia, the orientation of the main mosque dominates the orientation of the entire city. In the case of Cairo various parts of the city and its suburbs are oriented in three different qiblas. The new Fatimid city of al-Qāhira, founded in the tenth century, faces winter sunset, which was the qibla of the Companions of the Prophet who

erected the first mosque in Egypt in nearby Fustat some three centuries previously. The later Mamluk "City of the Dead" faces the qibla of the astronomers. The predominant orientation of architecture in the suburb of al-Qarāfa is toward the south, another popular qibla. The splendid Mamluk mosques and madrasas built along the main thoroughfare of the old Fatimid city are aligned externally with the street plan, and internally with the qibla of the astronomers: one can observe the varying thickness of the walls when standing in front of the windows inside the mosque overlooking the street outside. This is an area of the history of urban development in the Islamic world which has only recently been studied for the first time, not least because, prior to the discovery of the textual evidence, it was by no means clear which directions were used as qiblas; even if a qibla at variance from the true qibla was clearly popular, it was not known why. The first accurate longitude values of localities in the Islamic world become available only with the systematic scientific cartographic surveys of the eighteenth and nineteenth centuries. Thus most of the accurately computed qiblas of the medieval astronomers could be judged as being in error by a few degrees anyway.

Other Applications of Science to Daily Life

The Islamic laws of inheritance, based on prescriptions in the *Qurʾān*, are complicated, and their application involves some skill in arithmetic. Both legal scholars and certain mathematicians wrote on this subject, but only two or three simple works by legalists have been studied and until recently no research of consequence had been conducted on the large number of available sources. There is also a vast corpus of literature on weights, measures, and arithmetical techniques.

Muslims also developed geometric designs for the decoration of religious architecture and also secular artifacts. The acceptability of such ornamentation is discussed by various legal scholars,

but their writings have yet to be properly studied. Only two Muslim mathematicians are known to have included remarks on geometric design in their writings, a fact which confirms the suspicion that this was an art passed down amongst the practitioners. Some years ago a manuscript of an artisan's manual with guidelines for generating numerous patterns is now published.

The legal scholars of medieval Islam used methods for regulating the calendar and prayer times and for finding the sacred direction which were simple and adequate for practical purposes. Their ingenuity in coping with differences of opinion never lost sight of the basic purpose of Quranic and Prophetic injunctions. Some of the greatest of the Muslim scientists dealt with the calendar, prayer times, and the qibla, and in these areas, as in others, their mathematical creativity and their quest for greater accuracy was impressive. In later centuries (after the thirteenth), competent astronomers were appointed to the staffs of major mosques in order to advise on these specific subjects. But the solutions developed by Muslim scientists were invariably too complicated for widespread application in the medieval milieu. Although the scholars of the sacred law and the scientists proposed different solutions for the same individual problem, there are few records of serious discord between the two groups in the medieval sources. The legal scholars criticized mathematical astronomy mainly insofar as it was used by some as the handmaiden of astrology, which was an anathema to them. The scientists seldom spoke out against the simple procedures adopted by the legal scholars.

Religion and Science in Islam II: What Scientists Said About Religion and What Islam Said About Science

Anton M. Heinen

The interaction between religious life and scientific enterprise in the culture that evolved under the impact of Islam is one of the predominating themes in today's discussions and writings of Muslims all over the world. It has continued to be such ever since the beginning of the last century, when European forces, with their newly developed technological means, extended their rule over large areas with Muslim populations until then concerned only with the traditional values of their preindustrial communities. Today's revivalist Muslim leaders, themselves often engineers or trained scientists and not theologians, fight for a new society based on a harmonious practice of Islam and science. Or governments build mosques with technological showpieces (e.g., minarets with laser beams as indicators of the *qibla*, the direction of Mecca, as recently in Morocco), and museums and universities dedicated to the "Islamic sciences". The scientific achievements of the West are considered to be the inheritance of great Muslim sages of the Middle Ages. Thus modern technology cannot be a dangerous evil because it belonged to the Muslims first. But it has been alienated by the West, truncated from its heart, which is the recognition of Allāh, the Creator of all beings. This was the view of the influential leader of the Muslim Brothers, Sayyid Qutb (1906–1966). Although he was executed under Nasser's government in Egypt in 1966, his brief sermon on *This Faith, Islam* is still representative of some sections of opinion in the Muslim community.

Observers from the outside world, where the dispute between religion and science has largely turned into a relic of the past, if it does not lead into ethical discussions about the effects of

scientific and technological progress on human values, find it difficult to do justice to this preoccupation of their Muslim neighbors, which they usually interpret in analogy to apparently similar ideologies in their own realm, such as fundamentalism in America's "Bible Belt". However, the religious as well as the scientific realities involved differ greatly on both sides. Instead, the insights of the history of science as well as that of religion should be drawn upon when the relationship between the two fields is to be treated objectively. As the history of science has brought to light a whole spectrum of changing methods and conceptualizations that over the centuries have been interpreted as "science", so also "religion" has been described by its historians as being practiced variously by just about every people, culture, time, or even individual. Generalizations about the religious factor in human activities, in the West always identified with dogmatic teachings, are just as false as those about an unhistorically monolithic science, but even more widespread. The surprisingly bitter reaction to the attack of some European powers and individuals will be more readily understood if the interaction of science and Islamic religion, from the outset centered on increasing knowledge, is rightly appreciated.

The case of scientific technology probably was chosen as a favored battlefield because the Western critics, proudly flying the flag of enlightenment, had previously used it as a weapon against the Islamic religion. Thus, cultural and technological backwardness became a religious issue for Muslim intellectuals. Curiously enough, it was the philosophical and scientific work of Ibn Rushd (Latin Averroes, 1126–1198), who as "the Commentator" (namely of Aristotle) had been accepted as master by the European scholars throughout the Middle Ages, which stood in the center of this modern attack on Islam. That he had not been able to influence his co-religionists in the Islamic world to the same extent as the Jewish and Christian schoolmen in Europe was the main reason that Islam in the last century was made responsible for the worst obstruction against scientific progress. The main exponent for this attack was Ernest Renan's *L'Islam et la science*,

written in 1883; the Arabic writings of Farah Anṭūn in the journal *Al-Jāmi'a* (Cairo, 1902–1903), easily accessible for Egyptian intellectuals, made this attack on Islam even more effective. From then on, the relationship between science and religion, both seen in the crystallized and almost ahistorical notions of that time, was turned into the most crucial question for any global view of Islam in human history. The question was raised on more general grounds: "Why did the Muslims fall back, while the others made progress?" The more general and fundamental questions have stood in the foreground; the more particular ones, e.g., the Islamic position *vis-à-vis* alchemy, astrology, geocentric vs. heliocentric astronomy, or such consequential medical questions as anatomical dissections, preventive measures against epidemics, abortion, birth control, etc., have been strangely pushed into the background, although numerous treatises over the centuries have been written on them.

In defense, the beginnings of the spread of scientific activity in Islamic culture, and then its high period, were chiefly taken for reference, not the obvious stagnation in the later Middle Ages. The latter phenomenon has hardly been studied, and almost no convincing explanations have ever been proposed. But it is revealing that no responsibility for such an intrusion into scientific development has been assigned to the Islamic religious authorities, as has been the case of the Inquisition trials in Christian countries.

But, in confrontation with medieval historians centered on Europe, it was not easy to reclaim the scientific heritage for the Muslims, for this heritage was primarily seen as that of the ancient Greeks whose works had been translated into Arabic. And since these works, some centuries later, were again translated from Arabic into Latin, the Arabs apparently were assigned the humble role of transmitters only, like the merchants in an import and export business. For Renan, the cultural role of Islam was actually limited to the preservation of ancient culture for and transmission to Europe, where it would be revived. That such translations from pre-Islamic Hellenistic culture involved a heavy indebtedness was not denied by Arab historians. However,

in their view this ancient heritage was integrated into an already established Islamic society. As it is today, with more sources to judge by, the roots of the scientific movement in Islam itself are more generally recognized as having exerted a stimulating influence on the introduction of the more complete scientific heritage of pre-Islamic cultures: the *Qur'ān* and its exegesis, jurisprudence, philology, etc.

The first line of defense was taken up by such rationalist reformers as Shaykh Muḥammad 'Abduh (1849–1905). He argued that Quranic religion was in no way opposed to, but on the contrary totally in harmony with science. The guidelines of his argument were taken from the apologetic discussions about the necessity of miracles as testimonials for the true prophet: miracles supposedly revealed the divine nature of Jesus, the Son of God, while the Prophet Muḥammad had only referred to the factual evidence of the Arabic *Qur'ān* in support of his divine message. (Miracles like the splitting of the Moon by the Prophet, as they were described in popular literature, were apparently not considered in this argumentation of modernist theology.) That the fact of revelation, divine speech entering the limits of creation, or the *Qur'ān* as an inimitable revealed book, were proposed by the Prophet as the decisive miracle, or that creation and recreation after death were described as miracles permeating the whole of human existence, all these truly “miraculous” events apparently were not considered to interfere with the course of nature.

Unfortunately, 'Abduh's apologetic argumentation was later exaggerated by his disciple Rashīd Riḍā (1865–1935) who claimed science for Islam. In his commentary of the revealed book, all knowledge was traced to the *Qur'ān*, even modern technological and medical inventions. For example, the Arabic *Jinn* were identified with the microbes of contemporary medicine. But progress soon let such hasty identifications appear outdated, and today this unhealthy spirit of “Islamization” is much less prevalent.

More common, and truer to the revealed Quranic texts, is the derivation of an original

Muslim science from the so-called “sign-verses,” i.e., those verses that prescribe the inquiry into such signs in creation as the sun, moon, stars, earth, and sea, life in all its forms, in fact whatever enters the realm of human experience. Corresponding texts can be found in the works of Muslim scientists throughout Islamic history, in the *Taḥdīd nihāyāt al-amākin* (The Determination of the Coordinates of Positions for the Correction of Distances Between Cities) of the mathematician and astronomer ► [al-Bīrūnī](#) (973–1051), in the *Faṣl al-maqāl* (On the Harmony of Religion and Philosophy) of the philosopher Ibn Rushd (1126–1198), or the interviews of the living Nobel prize winner Abdus Salam. Such an inquiry, as should be noted against a frequent misunderstanding of Western scholars, was not to lead to higher developed proofs for the existence of God, for it would be contrary to the faith of Islam that such proofs should be needed. But Muslims of all times have interpreted the Quranic counsels of “considering the wonders of creation” as the most effective promotion of scientific research. The results were not predetermined; not even the existence of the Creator was imposed as the logical consequence of a binding argument. But the faithful scientist was to find himself placed in the more overwhelming presence of a personally approachable God Almighty. The inner spiritual motivations for an Islamic science, not the passing discoveries, were of the greatest significance.

How far along the way of an open and progressive science a Muslim scholar could be led by the sign-passages of the *Qur'ān* is best illustrated by Ibn Rushd's treatise *Faṣl al-maqāl*. Even though he was a high functionary of Islamic law at the court of the strict Almohad administration, Ibn Rushd wrote this work as a legal defense of objective and universalist scholarship. Beginning from the Quranic injunctions to respond with thought and inquiry to the wonders of creation, he gradually moved on to the defense of gradual progress beyond incomplete scientific results, relying in the process on the heritage of pre- and non-Islamic sages. Hence, the great lawyer could even accept preliminary results, teachings known to include errors. To tolerate such partially

erroneous theories, while always proceeding toward deeper insights, was for him a basic consequence of the human condition. While not denying prophetic revelation as the source of the Islamic religious movement, Ibn Rushd with this open system may be said to have reached the highest peak of the Islamic scientific worldview.

It cannot be surprising that natural research on the background of the Quranic finding of the Creator, whose inner nature is above all human speculation, in the signs he had placed for humanity into his creation, has sometimes been understood along Pantheistic lines. Knowledge did seem to acquire a higher character for salvation, or even a certain participation in the unitarian nature of the One God. Influential theologians like al-Ghazālī (1058–1111), but also leading scientists up to Abdus Salam in present times, insisted on Allāh's personal nature as Creator. Scientific disciplines, therefore, were to be used only for specific human purposes, and no one but God himself granted his highest blissful knowledge to the faithful who had clung to the fulfillment of his revealed will. Since God himself as Creator was also the author of all instruction, the growth of knowledge and the production of new inventions were not really possible for man restricted to his own created capacities.

But, as heir to a tradition of scholars who already had worked at filling a still Hellenistic science with Islamic spirit, al-Ghazālī also proposed the method of *Tafakkur*, a kind of meditation on the various phenomena of creation, which could lead to greater insights and more extensive knowledge, under the constant guidance of the Almighty. Such a method may have been at the root of the widespread mysticism of nature in Islam. As S. H. Nasr has observed, some of the greatest scientists in Islam (e.g., Quṭb al-Dīn ► al-Shīrāzī, AD 1236–1311) are known to have practiced Sūfism as well. But *Tafakkur* also presents a corrective for the unitarian view of Islamic science described above, Muslim thinkers asserted God's unity in all spheres of reality, thus reducing the multiplicity of created phenomena into a forced monism. The contrary can also be said, because by always keeping the spiritual goal of *ta'ẓīm Allāh* (Magnification of

God) in mind, the Muslim researcher, instead of closing it, would instead turn more and more leaves of Allāh's grand book of nature. The linguistic particularity of the Arabic language, always concentrating on individuality (*shawādh*), naturally could enforce this tendency.

It has become a standard argument that Islam needed such sciences as astronomy, mathematics, and geography for ritual obligations like the pilgrimage to Mecca, the establishment of the *qibla* (direction to Mecca) of new mosques, or even any prayer according to the traditional prescriptions. But some scholars feel this point should not be overstressed: even a legal authority like Abū Hanīfa (d. 767) warned that spatial orientation was not essential for the submission of the worshipper to the Creator, and numerous religious leaders maintained a quite relaxed attitude when confronted with greater mathematical exactness in the setting of the *qibla*. On the other hand, quite simple devices were sufficient for these needs. The number of treatises on the mathematical problems of the *qibla* are not necessarily in proportion to its importance for the Muslim community.

Of greater significance, and easily demonstrable, is the promotion of mathematical works by the theological principles of Islamic law. As the mathematician and astronomer in the Biblical tradition was encouraged by the saying that God had created the whole world with numbers (Wisdom 11,20), so the Muslim was convinced that the divine lawgiver had left nothing to the arbitrary decisions of sinful mankind, not even the shares of inheritance to be distributed among the members of a family: "...the male shall receive the portion of two females..." (Sūra 4, 175 ff). The natural consequence was the discovery and perfecting of algebraic rules which future lawyers had to learn for the administration of bequests; in other words, some mathematical instruction even entered legal schools usually blamed for having marginalized the rational and natural sciences. There it achieved full recognition as the respectable "science of shares" (*ilm al-farā'id*).

The most characteristic and generally applied argument in support of orthodoxy and

orthopraxis in Islamic intellectual history has certainly been the principle of *Sunna*. With carefully examined traditional reports it had to be established that questionable teachings or practices were sanctioned by words or actions/omissions of the Prophet himself or his Companions, or, in the case of Shiite Islam, the Imams. As this had already been done for the concepts and arguments of the theologians and jurists, the procedure did not stop at science, where it would seem to have been singularly inappropriate. Thus one of the most copied treatises of the Middle Ages, an indicator of its popularity, was the *al-Hay'a al-sanīya fī al-hay'a al-sunnīya* by al-Suyūṭī (1445–1505), a cosmographical work totally made up of well-attested traditional fragments of early theories.

The apparently simplistic view that truth can only be what has been taught or practiced by respected members of the Muslim community, testified to by an interrupted chain of trustworthy witnesses, may have been grounded in the deeper conviction that all values are sanctioned by the harmony with the laws of a well-established community. Scientific progress cannot be judged good and sane if it does not fit into the proven structures of a justice-oriented society or a healthy environment. In Islam this social order and the harmony with a God-created nature are directly derived from religion; hence, their demands on the work of the scientists belong to the religious, not the ethical or secular, realm.

Jurisprudence, no doubt, has been the most important discipline in the intellectual formation of the Muslims throughout their history. Some historians, considering the numerical superiority of law teachers and their students at the colleges and universities in Muslim lands, have blamed the lawyers for having pushed the sciences to the margins of academic institutions. On the other hand, hardly any other religious community has been so deeply formed by the ideal of realizing all its vital functions according to the principles of justice. The work of the scientists has not remained unaffected by this ideal. Thus long before Simon Stevin in his *Weeghconst* (Theoretical Statics, 1586) prepared the “democratization of science”, which eventually gave it a

special measure of vitality in Western nations, his Arab predecessor ► [al-Khāzinī](#) (fl. first half of the thirteenth century) had published in the *Kitāb mīzān al-ḥikma* (Book of the Balance of Wisdom) a remarkable memorandum on science's being rooted in an all-encompassing justice. This is, however, an aspect of the interaction of science and faith in Islam which has hardly been studied, in spite of its significance for the appropriation of technology by widely spread popular organizations, guilds, and Sūfī brotherhoods, or the stagnation up to modern times.

Religion and Science in the Native Americas

Åke Hultkrantz

If science may be said to be concerned with "observation, description, definition, classification, measurement, experimentation, generalization, explanation, prediction, evaluation, and control of the world," as it is in the *International Encyclopedia of the Social Sciences*, it is easy to conclude that all these practices have occurred among American Indians, mostly within a religious and mythological perspective. Some scholars presuppose that American Indians have lived in a natural-supernatural continuum where the distinction between this and the other world (however we care to define it) practically falls down. Others, including this author, are under the impression that the indigenous people postulated two experimental worlds, the natural world around them in everyday life, and the mysterious world of myth and religion which occasionally breaks into the natural world, for instance in dreams and rituals. In the long run this mysterious (supernatural) world seems to constitute the real, true world; at least some religious Native thinkers believe this is the case. It is not impossible that many Indian visionaries believed this without verbalizing their beliefs.

In any case, Indian observations and explanations have, in their own thinking, been linked to

religious evaluations. Everyday reality was mostly experienced from a profane point of view where experiences followed each other in a foreseen way. Where this was not the case, or uncertain courses of events and unknown places are met, the other dimension is resorted to. Since the latter dimension is the most difficult to understand, and rules humankind's life, the interpreters of that world, medicine men, shamans and priests, and artisans that catch symbols and spiritual realities, are more important than experts on the everyday world. We can state that in Native America the range of spiritual experts has been much wider than that of technological experts.

The anthropologist Paul Radin has shown that there exists what he calls "two general types of temperament" among, in particular, American Indians: "the man of action and the thinker, the type which lives fairly exclusively on what might be called a motor level and the type that demands explanations and derives pleasure from some form of speculative thinking." It is characteristic that in order to describe the thinkers and their accomplishments he turns to the specialists on religion (and then a bit arbitrarily joins "historians," i.e., mythological raconteurs, with such specialists of experimental religion as medicine men and shamans). American Indians are on the whole not skeptics, since dreams, hallucinations, and traditions of visits to the other world by eminent spiritualists give strength to their religious beliefs. Collective rituals give these beliefs a realistic stamp. Only when different religions collide and a relativism of values ensues do religious brooding, skepticism, and indifference take over. There is thus little space for other than religiomythical incitements in penetrating the marginal recesses of the empirical world.

The dominance of religious thinking in what science today would call secular matters is obvious in the fields of cosmology and medicine. There are two great world pictures in America. One is certainly the older one, with Paleolithic-Mesolithic origins and connections with the hunting tribes in the Old World. It depicts a Universe where the world pillar or the world tree forms the axis which connects heaven and earth. It is often said that this pole or tree is situated in the middle

of the world; its roots are fixed in the underworld and nourished by subterranean rivers or a well. Its top reaches the sky that rests on it. Sometimes the world column stretches through several skies until it reaches the highest sky. Symbols of the different species of animals living on different levels are supposed to dwell on the tree: lowest down snakes or fishes, on the earth level deer and buffalo, highest up birds like eagles and falcons. Some tribes relate that unborn souls inhabit the crown of the world tree. Other tribes believe that the world tree, that often has a forked top, is identical to the Milky Way which is "the backbone of the sky" and the road taken by the souls to the hereafter. The world has also formed the passageway downward for the gods when they cared to visit the ground and upward for the shamans when in their séances their souls went to the supernatural world to receive information of the gods (and, in some cases, to release a diseased person's captured soul from the realm of the dead). The world tree is ritually modeled in the middle pole of ceremonial structures, such as the Plains Indian Sun Dance hall, which is itself a ritual reproduction of the cosmos. The Sun Dance ceremony is a repetition of the cosmic creation.

The world tree expresses an inclination for a heavenly world. American high culture supplants the tree or pillar symbol with a temple mound, mostly a pyramid. On the top of this pyramid the gods have their habitats (read: statues), and many pyramids enclose the bodies of deceased princes. The sacred temple areas in Mexican pre-Columbian cities are modeled after the supposed heavenly geography.

The other world picture which has been distributed in agricultural areas has its parallels in the agrarian civilizations of the Old World. In this case the attention on the supernatural world is, at least partly, directed downward, to the underworld. Here is the place from which man, like the plants, once in mythic time came up, often climbing on a reed. Myths even talk of four successive underworlds, one darker than the other, or qualified through different colors. Inundating waters or other difficulties started the evacuation. Myths tell us that valuable animals, like the buffalo in North America, also came up from the

nether world. Men and animals appeared from a grotto which ever since has been said to be the center of the world. After death the living beings returned to the underworld, like the plant returns to it when it withers. The underworld realm of the dead is mostly the place to which shamans send out their soul to retrieve the lost soul of a sick patient. Some divinities, be it the lord-lady of the dead or the spirits of vegetation, may be found in the underworld.

These world pictures are supposed to be stable, as when the Lenape (Delaware Indian) Supreme Being with his hand holds the upper part of the world pole. However, in earthquake areas this is not the case. According to anthropologist Lowell J. Bean, the Cahuilla of Southern California believed

that all matter was subject to unpredictable change . . . For example, dramatic changes in topography are vividly and frequently recalled. . . This instability was true from the beginning. Creation of the earth and life itself was fraught with indecision, mistakes, and conflicts of power between the creator brothers.

This is a neat example of how environmental changes are referred to mythical incidents.

Also in another topic, medicine and medical practice, religion outbids what we might consider a more "scientific" approach. Certainly, there is, even behind supernatural gestures, the beginning of a systematic and naturalist treatment of sick persons in a simple hunting milieu. The herbalists who supply herbs, cobwebs, sap, or leaves for wounds, or handle internal medicine for the patient, follow what they have learnt or what their own experiences have taught them. Observation and practice over the years thus guided their use of natural medicine, and today's science of laboratory medicine can sometimes corroborate the positive medical properties of these medicines. If anything the choice of useful medicaments points out the scientific endeavors of American Indians.

However, there are other doctors as well, and their curing is considered more important. Medicine men and shamans invoke supernatural powers in order to deliver the sick from a serious disease (or a disease which they comprehend as

serious). Gods and spirits are then thought to be the active medical powers, and the disease itself may be a demoniac being. In other words, the more serious the disease is, the more frequently supernatural powers have to be invoked. Of course, even simple herbalist methods may be accompanied by religious blessings.

Such a continuum between this world and the other world may, superficially seen, seem to make the distinction between them invalid, but this is not so. American Indians have had recourse to systems which would not satisfy Western logic; their logic is often created from the needs of the situation. In religion, completely reciprocally exclusive belief chains may be resorted to, depending on the situation. In the same manner, Indians may interpret phenomena as derived from this world or the other world, but also, in single cases, see a continuous line between them.

As a further example of such thinking the hierarchy of biological masters may be mentioned. In many places in both Americas animals and plants are supposed to be controlled by masters who rule over them and own them. These masters may be animals of some sort, or supernatural beings. The Mataco in Argentina and Bolivia believe that herbs and trees are subordinated to their "owners," certain animals and birds. Thus, the wild red pepper is owned by the red-eyed dove. The dove in its turn obeys a lord of the forest who is also the lord of honey. We learn that the latter is a supernatural being, whereas the dove is a natural bird. In this connection it should be pointed out that in many places, scholars have observed a folk classification of natural plants and animals. Indian tribes have constructed taxonomies with a series of hierarchical levels. In these cases it seems that only natural species have been segregated. It is another matter when Plains Indian medicine men arrange their guardian spirits, which appear in animal disguise, in an order according to their efficiency: they are ranked as spirits, not as animals, and may be included in a hierarchy. It is a remarkable fact that this hierarchical thinking occurs in societies which are otherwise characterized by their equality.

We have seen how the world picture, or the view of the Universe, is arranged according to religiomythical models in original Native American thought. In addition to what was said above it can be noted that stars and planets are also included in these models. The sun and moon may be understood as divinities or symbols of divinities; the sun is often a manifestation of the Supreme Being, the moon a manifestation of Mother Earth, or the god (goddess) of vegetation. The planets and stars incarnate other supernatural beings, often the culture hero and hunting spirits. The Blackfoot and other tribes tell myths according to which the main actors are transformed into well-known stars when their adventures have finished. Among the Pawnee all dominant gods are stars, the chief one among them being the high god Tirawa who is identified as the North star. Thus, the stars are supposed to be living, spiritual beings, something which is also demonstrated in their movements over the sky. Such a portrait of the star charter is the presupposition of astrology. In the classical antiquity of the Old World some supreme power, or fate, ruled the star movements; in America, the prime movers could be the stars themselves, or some power behind the stars. In both worlds omens and policies were dictated by these powers, and thus what some call a pseudoscience, astrology, took form to find out the nature of these dictates.

Among the high civilizations, such as the Maya of Southern Mexico and Guatemala, parts of the clergy made observations of the sky for astrological purposes. It has been said that in Mesoamerica and South America people tracked the positions of the stars in order to know how they themselves should behave, when they should plant, and when they should perform sacrifices, whereas in North America the signs from the heaven were an aid to good living, not frightening information. This distinction is probably too exaggerated. In North America there was great fear when, during eclipses of the sun or the moon, the celestial body was supposed to be swallowed up by some monster.

Astrology has, all over the world, paved the way for astronomy; this is also true in North and South America. The great annual festivals,

the fertility ceremonies, and other occasions for ritual celebrations could begin when star constellations were favorable. The Tapirape Indians of the Amazonian forest know that when the Pleiades disappear in the west the rainy season is over. The prehistoric northern Plains Indians constructed ► [medicine wheels](#) on mountain tops (or, if there were no mountains in the area, on the open plains) which archeologists and astronomers interpret as calendar monuments, used for the determination of the summer solstice. For instance, the famous Medicine Wheel on the ridge of the Bighorn Mountains in Wyoming has the form of a wheel with a central cairn united with the peripheral stone ring through 28 spokes of stone. Other cairns are situated close to the periphery. From one of the latter cairns one can perceive the sun over the central cairn on Midsummer's Day. There are reasons to assume that the structure also had cultic functions. Its ground plan mirrors the world picture with the world pillar in the middle of the world, as was described earlier. Among other things, the 28 spokes correspond to the 28 roof poles of the Sun Dance lodge. This might also correspond to the 28 lunar mansions in Chinese, Islamic, and Indian astronomy.

In the matter of astronomical calculations the Maya were the masters. In order to arrive at exact computations they developed mathematics, used multiplication tables, and calculated the days of the year. With these means the Maya priest-astronomers managed to bring the Venus cycle into relation with the year, and they were also able to construct a table for predicting solar eclipses (although the latter were not always visible in the Maya area). Such eclipses were considered to be dangerous. The foreknowledge of the times they would appear made it possible for the priests to take action to help the threatened human beings.

Thus it appears that the beginning of science was motivated by its use for religious and ritual purposes. The Maya scholar, Eric Thompson, has this to say about the Maya intellectual achievements:

It is remarkable that the intellectual successes of the Maya were not (from our point of view) practical; they were the outcome of spiritual needs.

The Maya astronomers strove for knowledge, not as an end in itself, but as a means of controlling fate, a kind of astrology. There was, he felt, an orderliness in the heavens to which the gods conformed; once that was learned, he could predict the future through exact knowledge of which gods held sway at any given time, and influence it by knowing when and whom to propitiate.

It is also possible that the Maya writing with its multivalent hieroglyphs was first developed to serve sacerdotal ends. In any case, during the Classic Period, the Maya texts deal with astronomy, the connections between stars and gods, and associated ceremonies.

We could of course argue that there was in aboriginal America an appreciation of knowledge and learning that had no religious causation; but it can be scarcely understood as a scientific ambition. Skills in technology, and inventions (Inca road building, Maya corbelled vaults, Mexican wheel toys, etc.), rarely deserve this designation either. Inuit coast maps are a wonder of precision and may pass for art. Truly profane science was not part of the American Indian world.

Reproduction in Japan

Noriko Tsuya

Faculty of Economics, Keio University, Tokyo, Japan

This entry focuses on reproduction, the process by which human generations succeed each other, in Japan during the early modern period. This period is also known as the Tokugawa era that began in 1603 and ended in 1868. Reproduction concerns the number of surviving children, taking into account not only the number of children born to each woman or couple, known to demographers as fertility, but also infant and childhood mortality. In contrast to historical Europe in which births were in general recorded without omission in parish registers, annual local household registers called *ninbetsu-aratame-cho* or *shumon-aratame-cho*, which are the major data sources for demographic studies of Tokugawa Japan, only recorded infants who survived to the first enumeration after birth (Smith, 1977, pp. 59–64; Tsuya & Kurosu, 2010). Since this partial omission of births distorts nearly all conventional fertility measures, when we look at reproduction, we have to consider both fertility and infant mortality due to under-registration.

Although seemingly a data problem, differences in recording births between the historical West and preindustrial Japan reveal different perceptions of what constituted “life” in the context of different reproductive cultures. Because Christianity regards the moment of conception as the beginning of life, intervention in procreation was deemed unacceptable in the historical West (Lee, Wang, & Tsuya, 2010). Furthermore, since the

bond between a husband and a wife was the foundation of the Western family and the conjugal bond was legitimated by procreation, interference in reproduction was probably inopportune from the perspectives of couples as long as procreation did not limit their economic situations seriously. In contrast, in preindustrial Japan a life in a fetus or a newborn was viewed as flux and therefore not considered fully human (LaFleur, 1992). The view of liquid life coupled with the collective orientation of families as a lineal entity allowed and even encouraged direct intervention in reproduction through infanticide and induced abortion (Derosas & Tsuya, 2010; Taeuber, 1958, pp. 29–30).

Reproduction in preindustrial Japan is characterized by relatively early and universal marriage, especially among women, and tightly controlled reproduction within marriage. The mean age at first marriage among women in different parts of rural Japan in the eighteenth and nineteenth centuries is estimated to have ranged from around 15–16 in the northeast to around 25–26 in the southwest (Kurosu, Tsuya, & Hamano, 1999; Tsuya & Kurosu, 2010). Though varied widely by region and time period, the timing of female first marriage in eighteenth- and nineteenth-century Japan was earlier than in preindustrial Western Europe where the mean age at first marriage typically ranged from women's late 20s to 30 (Dupaquier, Helin, Laslett, Livi-Bacci, & Sogner, 1981; Flinn, 1981). Marriage was also universal in early modern Japan. The proportion of women who never married was below 5 % at age 50 (Tsuya, 2001; Tsuya & Kurosu, 2010), posing a clear contrast to historical Western Europe in which a considerable proportion (roughly 10–30 %) of women stayed unmarried until the end of their reproductive years. Clearly, a relatively early and universal female marriage pattern prevailed in preindustrial Japan.

Marital reproduction was tightly controlled in early modern Japan although there were considerable regional and temporal variations (Hayami & Kurosu, 2001; Saito, 1998). Studies found that the level of marital reproduction in Tokugawa Japan was in general lower than those in many preindustrial European communities.

For example, the total marital fertility rates (TMFR) for women age 20–49, which is a common indicator of the level of marital fertility used in historical demography, ranged from 2.8 to 5.9 in farming villages in northeastern and central Japan during the eighteenth and nineteenth centuries (Tsuya & Kurosu, 2010). The TMFR was in the range of 7.3–8.7 in nineteenth-century rural communities in eastern Belgium, southern Sweden, and central Italy (Lee, Wang, & Tsuya, 2010). The relatively low level of marital fertility in Tokugawa Japanese villages may have been due in part to the above mentioned under-registration of births, which is estimated to be around 18 % of all births (for specifics, see Tsuya, Campbell, & Wang, 2010). Even taking this under-registration into account, however, the level of marital reproduction in early modern Japan seems to have been still lower than in many parts of historical Europe.

Using the two parameters – M and m – derived by Coale and Trussell (1974, 1978a, b), we can quantify the degree of age-specific control of reproduction within marriage and the level of marital reproduction. The M parameter indicates the level of marital fertility relative to the natural fertility standard, and the m parameter indexes the extent of deliberate control of marital fertility depending on family size. Studies found that the level of marital reproduction was indeed low in rural communities in Tokugawa Japan (Tomobe, 1991; Tsuya & Kurosu, 2010): as measured by M , it was roughly 30–60 % lower than the natural fertility standard. On the other hand, the estimated values of m for these communities indicate a moderate degree of reproduction control depending on family size. These studies therefore suggest that couples in early modern Japan controlled reproduction not only by limiting their family size but also by spacing children.

A consensus emerging from accumulated evidence covering a variety of Tokugawa Japanese villages is that marital reproductive control was done primarily through infanticide, and the way it was used was influenced by family-related factors such as the number of surviving offspring, their sex, and the timing of birth (Derosas & Tsuya, 2010). Some studies suggest that infanticide was practiced only after couples achieved their desired family size

(i.e., parity specific) and primarily against female infants (i.e., sex selective) (e.g., Hanley & Yamamura, 1977, pp. 226–232; Taeuber, 1958, p. 30). However, other studies found that infanticide was not always parity specific or limited to female infants. Rather, it was practiced flexibly to achieve the desires of couples and their households in terms of the size, sex composition, and sequence of progeny (Derosas & Tsuya, 2010; Smith, 1977, pp. 59–85; Tsuya & Kurosu, 2010).

Although a general agreement has not yet been reached as to whether or not deliberate control of marital reproduction was specific to family size or sex selective, empirical studies generally agree that infanticide was practiced in all classes of the Tokugawa peasant population and that it was used not only in times of economic difficulty but also in good times (Hanley & Yamamura, 1977, pp. 226–266; Saito, 1992; Smith, 1977, pp. 59–85; Tsuya & Kurosu, 2010). These studies therefore suggest that deliberate reproductive control by rural couples in early modern Japan was not a desperate response to the inexorable pressure of poverty and starvation at the time of economic hardships caused by famines and crop failures. Rather, it seems to have largely been couples' calculated behavior intending to improve the living standards and well-being of their progeny and household. The traditional Japanese term referring to infanticide – *mabiki*, literally the culling of seedlings – clearly indicates such intentions. Just as farms yield a better crop if certain seedlings are removed, couples might have desired to cull some infants to ensure the overall better quality of their surviving offspring. A trade-off existed between the benefits of having additional children and the alternative of conserving wealth to maintain or improve the family's living standard, and couples in preindustrial Japan often chose to control the size and composition of their offspring.

Rice Fields Reclamation in Southern India

K. T. Rammohan

Backwaters are large water bodies that are receptacles of rivers but contain saline water as they are connected to the sea. The Vembanad backwater system in far southern India covers an area of over 21,000 ha, measures 96.5 km in length, and is 3–8 m deep. Designated as a Ramsar site in 2002, the Vembanad is the largest estuarine system on India's western coast and as a transitional ecotone between land and sea, offers protection to innumerable living organisms, including clams and waterfowl (Nair, 2003). Population expansion and economic pressures of commercial agriculture and tourism, however, have put pressure on the backwater causing it to considerably dwindle over time (Narayanan, 2003).

While reclamation of Vembanad backwater for habitation and cultivation has a history that dates back many centuries, the scale of operation was small until the nineteenth century. From this period, Travancore was rapidly drafted into the world economy as a source of varied goods: coffee, tea, coconut oil, coir, and later rubber. It was crucial for the export economy to be price-competitive in the international market. Export production was labour intensive. To keep prices low, wages had to be kept low. This in turn required keeping food prices under check. However, the demand for rice was rising and its supply was falling. Besides normal demographic expansion, the immigrant workforce in the plantations

marked new demand. The relocation of agricultural workers to coir weaving factories in the coastal urban centres also possibly raised the demand for rice. Earlier, in the countryside, their food comprised some rice and a large share of tubers. In the town, lacking access to tubers that were not a marketed commodity, people substituted rice. As demand for rice rose, its supply fell. This was mainly due to the decline of hill cultivation of rice consequent to the setting up of plantations (Rammohan, 1996).

The princely government of Travancore sought to address the growing mismatch between supply and demand of rice in three ways: import of rice from Bengal, Burma, and Siam; propagation of cassava as a rice substitute; and encouraging the creation of new rice lands by reclaiming the Vembanad backwater. Large-scale reclamation began towards the late nineteenth century, with the princely government granting short-term exemption from tax on reclaimed lands and extending loans at concessional rates to the cultivators. Even with cheap and servile labour, reclamation was expensive. Usually one person was given permission, but he carried out reclamation by forming partnerships with a few others. Networking was mostly confined within a caste or community or among castes and communities of similar social status. Nayars and Christians, jointly and severally, floated most of the partnerships. Lower castes and communities lacking financial resources and influence in government could not undertake reclamation. Workers of Pulaya and Paraya castes, considered 'untouchable' by their higher caste landlords, did most of the work. The technology of reclamation also is indebted to these castes, especially Pulayas, who had long resorted to reclaiming shallow backwaters for cultivation, as they owned no land themselves.

Reclamation occurred during the summer when water level in the lake dipped. It involved two major operations: building a circular dyke (outer main dyke or ring dyke or *mata*) to enclose the backwater area proposed to be reclaimed and draining water out from the enclosed area. Dykes had to be built where water was 8–10 ft deep. This involved several stages. First, coconut palm trunk

piles in two parallel lines were driven into the bed of the backwater area to be reclaimed. These were fenced with ► **bamboo** screens on either side. The space enclosed by the bamboo screens was then tightly packed with clay, sand and brushwood. Clay had to be lifted from the lakebed at a depth of 10–12 ft and transported by country boats to the site. The dyke-enclosed area was then drained by using an array of waterwheels of different sizes, mounted one upon the other, operated day and night. After draining the area, usual agricultural operations could be commenced. With high water levels surrounding the field and the lake being prone to tides, constant vigil had to be maintained against any breach in the dyke. Land and water management was central to cultivation. All operations, including ploughing, sowing, weeding and harvesting, were dependent on timing and any delay could ruin the crop.

Rice cultivation in reclaimed lands was highly labour-intensive and its success depended on the availability of a captive workforce round the clock. Male workers built and maintained the dykes, and ploughed the field; the rest of the operations were mostly done by women. These workers were initially slaves and their masters were mostly members of upper castes like Brahmins and Nayars and communities like Syrian Christians. From the mid-nineteenth century, with the abolition of slavery, they were partially liberated but were still attached to the masters and their land. As land changed hands they had new masters. Some of them were settled in thatched mud huts in the master's homestead so that their services could be had anytime in the day or night. Others were settled on or near the dyke so that they could keep vigil over the dyke in times of heavy rains and act immediately if a breach occurred. The ring dykes demarcated individual fields while most fields were protected by outer dykes, built and maintained jointly by the farmers.

During the early years of reclamation, water was drained by using waterwheels made of wood. With the introduction of mechanical pump sets towards the end of the nineteenth century reclamation activity received a further boost. While earlier, only small blocks of 40–60 acres used to

be reclaimed, large blocks of hundreds of acres could now be reclaimed. Over 5,000 acres were newly reclaimed. The first pump sets that were introduced during the late nineteenth century were worked by producer gas and those introduced in the early decades of the twentieth century were run by kerosene or diesel. A British engineering firm based in Cochin, Geo Brunton Company, boat builders and operators of steamboats, introduced the first pump sets. The company hired these out to farmers. The company's men, many of them Anglo-Indians, operated the pump sets. With increase in demand, new suppliers like Marshall Sons and Company of Edinburgh operating through its branch at Madras also entered the scene (Rammohan, 1996).

Agricultural operations in the reclaimed tracts began in January or February. The field was ploughed using bullocks or oxen as draught animals. The soil of the reclaimed backwater was acidic and to neutralise it, lime was applied. The field was then flooded by opening the sluices in the dyke. The field remained submerged throughout the south western monsoon (June to August). By August when the water receded the field was again ploughed. This was a difficult operation as the worker had to wade through waist-deep and muddy water with the draught bullock or buffalo. Following this, the outer dykes were repaired and waterwheels set up at different points. The wheel was mounted vertically on a horizontal axle. The wheels were of different sizes; the number of spokes was usually in multiples of 6 and ranged from 6 to 36. To drain large areas an array of waterwheels, arranged in ascending order of size was used. The wheels were operated by gangs ranging from eight to ten workers, who perched themselves on ► [bamboo](#) scaffolding and pedalled the water away. This was hard labour and work was carried out in four shifts. The workers ascertained the time by looking at the sun, moon and stars. Alternatively, a half shell of coconut with a fine hole pierced at its bottom was used like an hourglass with water substituting for sand. The shell was placed in water and when water entering from below filled it entirely it was reckoned as a unit of time. Drainage operations were conducted for many fields at a time. As water

levels receded, the inner dykes and irrigation channels were repaired. The soil was then raked with a harrow, weeded and worked into a soft puddle. Water was then let into the field up to knee-depth. Sowing was done in October or November after the monsoon subsided. Seeds, sprouted in screw-pine bags, were broadcast in water. The field was then completely drained and kept dry for a week. Water was then let in, and when seedlings were about a month old, some transplanting was done to reduce the unevenness resulting from broadcast sowing. The field was completely drained after transplanting and manure – cow dung, green leaves, hay, and ash – applied. Pesticides were not used. The most common pest was a worm. As water level in the field rose, the worm crawled up and positioned itself on the edge of the leaf-blade. The worms were swept away into a basket using a stick or a broom. Water was let into the field at regular intervals till the harvest, which occurred in February or March. The ear heads were garnered with sickles and threshed with feet. The grain was winnowed and sun-dried on the threshing floor and conveyed to the granaries in country canoes. The grain was boiled, sun-dried and pounded by hand into rice. In certain parts of reclaimed areas, a deep-water variety of rice was cultivated. Its ear heads floated on the surface of water and were harvested from the canoes (Pillai and Panikar, 1965; Tharamangalam, 1981).

Rice in Africa

N. M. Nayar

Tropical Botanic Garden and Research Institute,
Trivandrum, Kerala, India

Introduction

Rice and wheat are the most important food crops of humankind. Both contribute about 21 % each of the total energy consumed by humans (Food and Agricultural Organization [FAO], 2009). However, between the two crop plants, rice is the more important one. It is the staff of life of humans, as it constitutes the staple food for more humans than any other crop.

Among all the crop plants, rice shows the widest adaptability. It is grown in more diverse environments than any other crop plant – from 4 m below sea level to the snowbound regions of Japan and Central Asia – from 53° North latitude to 35° South latitude (Lu & Chang, 1980). It shows a wide range of maturity also, from 65 to 70 days up to 330 to 360 days (Nayar, 2014).

Cultivated rice consists of two species, the universally cultivated Asian rice, *Oryza sativa* L. and the African rice, *O. glaberrima* Steud., whose cultivation is limited to tropical west Africa. The two rices belong to the genus *Oryza* L., tribe *Oryzeae* Dumort., subfamily Ehrhartoideae Link., family Poaceae Barnhart (synonym, *Gramineae* L.), order Poales Small, division Monocotyledonae, and class Magnoliopsida (Angiosperm Phylogeny Group [APG], 2009; Grass Phylogeny Working Groups [GPWG], 2001).

Rice is not a major crop in Africa, when the continent is considered as a whole. It ranks only fifth in the area under cultivation in the continent after maize, sorghum, millets, and cassava (cf. Nayar 2014). It occupied in 2013 only 6.6 % of the net cropped area in Africa and produced only 3.9 % of the global production with 29.3 M t rice paddy (FAO, 2007, 2009; FAOSTAT, 2014) (Table 1). At the same time, the rate of increase in rice production has been the highest in Africa since 1961 – with CAGR (compound annual growth rate) of 31.2 % versus 22.2 % globally (Nayar, 2014). The consumption rate of rice is also increasing most rapidly in the continent. For this, it imports as much as 60 % of its annual requirements of rice.

The present rice supply in Africa is only 23.3 kg/head/year (vs. 54.0 kg/head/year in the world) in 2011 (FAO, 2014). There is however much variation in rice consumption patterns in different regions of the continent. They are (in kg/head/year) as follows: Africa, 23.3 kg; Eastern, 15.3 kg; Middle, 13.9 kg; Northern, 16.3 kg; Southern, 16.1 kg; and Western, 39.5 kg (data for 2011, FAOSTAT; cf. Table 2 for latest data.).

Even within different regions, there is considerable variation in consumption patterns among countries (Tables 1 and 3).

Rice constitutes the staple/secondary staple food (a food item that provides 10 %/5 % energy/head/day) in 26/40 countries/entities in the continent (FAOSTAT, 2014). The daily percapita energy consumption varied from 101 kcals (5.4 % Middle Africa) to 1,038 kcals in Madagascar (102.1 kg annually, 48.1 % energy/day) (Nayar, 2014).

Egypt is the only country in the continent that produces more rice than it consumes. Cameroon in West Africa is almost self-sufficient in its rice requirements. All the other countries depend on imported rice to meet their requirements.

History

The earliest record of rice in Africa is that of Alexander the Great in 332 BCE, who had

brought it to Africa after his conquest of India, but rice did not get established then. Later, the Arabs introduced rice cultivation into Egypt in the seventh century CE. Rice cultivation became widespread with the increase in the Arab and Muslim influences from the tenth century CE (Nayar, 2010).

There is some prehistoric evidence about the introduction of rice into the Cyrenaica (Sudan) in 332 BCE, as mentioned by Pliny, the Greek geographer and historian (64 BCE–24 CE) (Lewicki, 1974). But this has not been confirmed by archaeological evidences.

The earliest archaeological record of rice in Africa has been obtained from the Roman ports of Berenike and Myos Hormos, both, in the Egyptian Red Sea. This is dated to the first century CE. These were entrepôts for goods required for the Roman Empire. Goods from India and East Africa used to be exchanged here with those from Rome.

There are three other archaeological reports of rice from Africa, all from Inland Niger Delta (IND) in tropical west Africa. They are all dated between 1000 BCE and 50 CE. One site yielded wild rice, and the other two were claimed to be of

O. glaberrima, the African cultivated rice. But there have been various problems in their identification (Nayar, 2014, for full details).

The east coast of Africa in general, and Madagascar in particular, has had a long history of maritime contacts with south and southeast Asia from prehistoric/early historic times. In Madagascar, there is an overwhelming influence of oriental contacts, particularly with present-day Indonesia. Even the language that is spoken there is Malagasy, which is a variant form of an Indonesian language. Most of the southeast Asian crops including rice have been cultivated there from very early times. Portères (1955) recorded that names of several rice landraces of the Island resemble those of south and southeast Asia.

The situation prevailing in tropical west Africa is comparable to that in Madagascar, but to a much less extent. This is so especially in the coastal regions of south and southwestern tropical Africa. Part of this coastal region is even known as the Rice Coast. Here, oral history and traditions indicate that this region might have had various Asian influences from very early times. Some of the ethnic or language groups of the region have a long history of rice culture. The traditional rice landraces of the region here possess red pericarp, and the local people traditionally prefer parboiled rice. Both these customs are widely prevalent in some regions of south Asia, such as in Kerala, the Konkan Coast, and parts of southeast India adjoining Bangladesh (Nayar 2014). Some authors have even proposed that rice was introduced into this region in very early times either overland across tropical Africa from Madagascar, or by sea round the Cape (Carpenter, 1978, Nayar, 1973 for instance). It was from this region that African rice *O. glaberrima* was first discovered and named.

Portères, the noted botanist from France, spent his career working and writing on both the African rice species. When Linnaeus first described the genus *Oryza* in 1753, he had identified only one *Oryza* species, the universally cultivated Asian rice, *O. sativa* L. Then Ernest von Steudel (1783–1856) described the African rice, *O. glaberrima* Steud. in 1855 AD, from a specimen collected by a French navy commander

Edelstan Jardin during 1845–1848 from the West African coast – actually, from Loess Island, off the coast of Conakry (in present-day Guinea). Jardin had identified it as *O. sativa* (Portères, 1955). Prior to Jardin, Leprieur, a French navy pharmacist had collected some rice specimens during 1824–1829 from Cape Verde, near Dakar (in present-day Senegal). Jardin prepared a herbarium sheet of his rice collection with two rice panicles and identified them as *O. sativa*. Portères (1955) found that one panicle was actually of *O. glaberrima*. This has become thus the first herbarium specimen of *O. glaberrima*, the African rice.

As the Latin name of the African rice implies, *O. glaberrima* is characterized by glabrousness of the spikelet, leaf, and some other plant parts. Typical African rice also possesses short ligules and red pericarp, and secondary branches are nearly absent in the panicles. In all other aspects of gross morphology, African rice looks similar to Asian rice.

At present, it is difficult – almost impossible – to find typical African rice. Most parts of tropical West Africa were in the possession of various European powers until the 1960s. After the end of the First World War (1914–1918), all these powers were promoting only Asian rice in their various agriculture development programs in their respective colonies. Thus, Asian rice got substituted for African rice. Second, natural crossings take place between the two cultivated rice species, which has all but eliminated pure forms of African rice.

Portères published early in his career that African rice arose in the Inland Niger Delta (IND) 3,500 years ago from the locally widely occurring annual species, *O. barthii* (then known as *O. breviligulata*) (Portères, 1962). He proposed further that African rice had two secondary centers of origin, the upper Guinea highlands and the region between the Casamance and Gambia rivers, both in tropical West Africa. He based his proposition partly on linguistic grounds and partly on archaeological evidences. Portères associated the time of origin of African rice with the time of installation of the giant stone structures, commonly known as Senegambian megaliths.

Portères (1962) papers have been severely criticized by both archaeologists and linguistic scientists. The age of these megaliths has since been determined to be between 200 BCE and 800 CE (Gray, 1962; Posnansky & McIntosh, 1976).

Unfortunately, all the literature that mentions African rice origins have been quoting only Portères (1962), oblivious of the criticisms that have been raised by numerous authors and scientists beginning with Gray (1962). Likewise, an alternative proposition on the origin of African rice from Asian rice and of *O. barthii* being the hybrid derivatives of *O. sativa* and *O. glaberrima* (Nayar, 1973) has not also received much attention including any repudiation of this proposal. Nayar (2010, 2012) has provided further evidence in support of this contention and also with the closely related annual wild rice species, *O. barthii*. Semon et al. (2005) have provided experimental evidences for this situation, albeit in another context (cf. Nayar 2014).

Current Rice Research in Africa

Most of the research on rice in Africa is now being carried out by either the International Rice Research Institute, Los Banos, The Philippines, which operates some cooperative programs with some countries in Africa, or the African Rice Center Cotonou, Benin (AfricaRice). Both are constituents of the CGIAR (Consultative Groups on International Agriculture Research). AfricaRice presently operates in over 24 countries in Africa. It is now primarily engaged in improving African rice. NERICA rice is the acronym for NEW RICE for Africa. It was the result of interspecific hybridization between African rice and Asian rice. However, the NERICA rice carries less than 10 % of the genetic material of African rice (Nayar, 2010). The newer series of rice are expected to contain higher levels of genetic material.

Egypt possibly is the only country in Africa having its own rice research program. Incidentally, Egypt is the largest producer and the only rice exporting country in Africa.

Rice Introduction into the New World

An important aside is the finding that rice was first introduced into the Americas not by the Europeans from Europe in the sixteenth to seventeenth centuries, but earlier by the African slaves of west Africa. Many of the slaves had carried rice with them for their personal use and/or for cultivation (Carney, 2001). West Africans carried rice not only to the present-day USA, but also to South America, especially the Guyanas.

Rice in Africa: The Future

We stated in the beginning that both the rates of increase in production and of consumption of rice have been the highest in Africa. Presently, it is importing almost 60 % of its annual requirements. The present yield levels in Africa are dismally low. We can only hope that with the intensification of R&D efforts on rice by the IRRI and AfricaRice, the continent will soon be in a position to be self-sufficient in its requirements in the medium term. This requires a considerable infusion of capital, for capacity building of both humans and infrastructure and also for meeting the recurring expenditure.

Africa is very rich in natural resources. Unfortunately, because of various social and political issues, these resources are not being put to productive uses. We can only hope this situation will improve in the future.

Rice in China

Hsiao-chun Hung

Australian National University, Canberra, ACT, Australia

Rice is a staple food for half of the world's population, and it has been a significant icon of Chinese culture for thousands of years. So far

the earliest written Chinese character of “wild rice” (秼) was recognized as  on an oracle bone of the Shang dynasty (1600–1046 B.C.), and the first “rice” (稻) was identified as  or  inscribed in a bronze of the Western Zhou dynasty (1046–771 B.C.). Long prior to any written records, archaeological evidence indicates the earliest harvesting of wild rice can be traced back to more than 10,000 years ago in southern China. The origins and developments of rice cultivation in China have a very deep root and a long process of evolution, closely linked with technological advances and the unique characters of Chinese life and cultures.

Origins and Early Developments

Rice is a cereal crop that produces edible seeds of grain. The seed can be eaten in its natural “wild” form, but rice potentially can be more productive and reliable as a staple crop in its domesticated form. Fully domesticated morphologies of Asian rice emerged in China as *Oryza sativa* var. *japonica* through multiple stages of crop processing (threshing, winnowing, sieving, dehushing, and hand selection) and over the course of many generations. In a natural condition, the seeds are easily shattered as part of their dispersal for regrowth, but over time, people selected for nonshattering varieties that could be stored safely for long periods such as the seasons between harvests. Additionally, people learned how to manage a well-watered environment for healthy growth and then eliminate the water supply for an artificially induced production of the edible seeds. These manipulations led to genetic transformations of rice, as well as to opportunities for various technological, economic, and social developments among rice-growing people.

Archaeological evidence so far reveals plentiful examples of wild and domesticated rice in several parts of China, but an exact point of origin (or multicentric origins) for domestication has been uncertain. The oldest preserved specimens are dated about 12,000–8000 B.C. in several

limestone caves in the foothills of the Nanling mountain range, but these specimens probably were wild *Oryza*. The middle-lower Yangtze River traditionally is viewed as the heartland of domesticated rice in China, where accordingly evidence of rice cultivation has been dated to about 8000–5000 B.C. The ancient origins may have been more complex, as morphologically domesticated rice has been found at comparable early dates elsewhere outside the Yangtze Basin, for instance, about 7000–6000 B.C. in sites of the middle Hanshui Valley and Huai Valley, located between the Yangtze and Yellow Rivers.

Regardless of debates about the point(s) of origin, the middle-lower Yangtze region contains several sites that together represent different stages in a long sequence of rice domestication. Here, rice farming can be seen as having developed in close integration with social life over a few thousand years. In the lower Yangtze, the abundance of rice is hinted at by the considerable quantities of rice husks incorporated into the clay of earthenware pottery as early as 8000 B.C. at Shangshan. Very dense concentrations of rice phytoliths have been found in the cultural layer of Xiaohuangshan, c. 8000–6000 B.C. Thousands of rice husks were found at the site of Kuahuqiao dated 6000–5000 B.C. In the middle Yangtze, as early as 7000–6000 B.C., preserved rice specimens are numerous at Pengtoushan. Nearly 20,000 rice husks and grains were collected from one small excavation at Bashidang, identified as an archaic type of cultivated rice, but the morphology differed from the present-day *indica* and *japonica* varieties (Zhang & Pei, 1997, pp. 36–41). Although those ancient rice grains unearthed from 8000 to 5000 B.C. appear to be wild-like (Crawford & Chen, 1998, Fuller et al., 2009) rather than fully domesticated, the impressive quantities found in the sites suggest that deliberate food production already was beginning at this time.

Definite nonshattering domestic forms of rice were prevalent by 4000 B.C. (Fuller et al., 2009). The oldest known traces of actual rice fields have been identified in the middle and lower Yangtze, at least as early as 4500–4200 B.C. These small fields probably were used by individual households, as

they typically enclose only 3–5 m² each, surrounded by low earthen banks. Examples in the lower Yangtze are found at Caoxieshan (Zou et al., 2000, pp. 97–113) and Chuodun (Ding, 2012), dated about 4200–3000 B.C. (Fig. 1). In the middle Yangtze, similar small rice fields have been reported at Chengtoushan, dated about 4500–4000 B.C. (Nasu, Gu, Momohara, & Yasuda, 2012). Large numbers of spades made of bone or wood come from other similar-aged sites in the lower Yangtze.

Increasing Productivity

Stone implements of plow cultivation first appeared about 4000–3300 B.C. and became well developed by 3300–2400 B.C. in association with the Liangzhu culture of the lower Yangtze, known for its marvelous artworks of jade, silk, and lacquerware and complex social structure. In a practical sense, plow cultivation enabled people to work in much larger fields than previously was possible by use of wooden and bone spades, and the total harvest output in theory could support a larger population. At the Maoshan site, more than 55,000 m² of ancient rice paddies has been documented (Fig. 2). At least as early as 3000–2600 B.C., the individual rice plots varied in size, as small as 1–2 m² but remarkably as large as 30–40 m², in rectangular or irregular rounded shapes. After 2600–2400 B.C., the rice fields were designed to incorporate river courses and embankments, irrigation channels, and paddy embankments (Fig. 3). So far, nine embankments between the paddies have been identified in this later stage of Liangzhu culture at the Maoshan site, and each unit enclosed about 1,000 m². Judging by the characteristics of rice phytoliths and spikelets, an estimated 221 kg of rice could be produced for each 1,000 m² area in the later stages of the Maoshan site, about 2.2–2.5 times higher than the yields in earlier Hemudu phase (c. 5000–3000 B.C.; Zheng et al., 2014). The large quantity of rice output very likely was one of the main factors in the Liangzhu culture's transformation into an elaborate social structure with ranked status and overt displays of wealth

Rice in China,

through artworks. Today, many Chinese scholars regard Liangzhu as the earliest kingdom in China.

With larger rice fields, irrigation systems developed for controlling flows of water. Since the Spring and Autumn Period (770–476 B.C.),

several national-level irrigation systems and water conservancy projects were developed for rice farming in China. The Dujiangyan (都江堰) irrigation system in Sichuan, an infrastructure was built in 256 B.C. during the Warring States

period, and it still is used today to irrigate over 5,300 sq km of farming land in the region. Many of these irrigation infrastructures meanwhile facilitated transpiration in ancient China.

By 700–600 B.C., iron tools and animal-driven devices vastly increased farming productivity, chiefly for rice. Some bronze implements already had made significant impacts at least as early as

Rice in China, Fig. 5 A ceramic funerary object, depicting a grain-processing workshop, unearthed from Sijangou, Jiyuan, Henan, showing a rice pestle and a winnowing device with two workers of Western Han attire, dated more than 2,000 years ago (Henan Museum)

1700 B.C., but iron tools were much more effective after the Spring and Autumn Period and best documented during the Han dynasty period of 206 B.C.–A.D. 220. Detailed scenarios of rice farming were recorded in Han period mural tombs, portraits on stones and bricks (Fig. 4), funerary objects, and ancient Chinese documents. *Si Sheng Zhi Shu* (汜勝之書, *Book of Si Sheng Zhi*) is the oldest known book about agriculture in China, presenting the details of the principles, methods, and timing of cultivation, as well as strategies of harvest and hoarding for 13 types of crops, including rice. The same book documented the techniques of water temperature control for rice paddies. Notably during the Han dynasty period, various new technologies were being developed to improve agricultural pursuits, such as a multiple tube seed drill for tilling soil and snowing seeds simultaneously, water lifting devices for irrigation, and winnowing devices and a water-driven pestle for grain processing (Hsiao & Yan, 2014; Figs. 5 and 6). Since then, technological inventions have continued to characterize much of Chinese history.

Dispersals to Other Regions

After 3000 B.C., rice cultivation was introduced into most parts of China and farther into

Rice in China, Fig. 6 Water-driven pestle for grain processing, illustrated in the book of *Tiangong Kaiwu* (天工開物, *The Exploitation of the Works of Nature*, by Song Yingxing in Ming dynasty). This type of pestle can be traced back to the Han dynasty

Rice in China, Fig. 7 A modern Vietnamese farmer with her plow and cattle working in a rice paddy field

neighboring regions, in some cases involving migrations of people and lifestyle along with the materials, knowledge, skills, and mechanisms of rice farming and processing. From the middle-lower Yangtze River, southern-moving routes were coastal into Fujian and Guangdong about 3000–2500 B.C., as well as inland into Guangxi and Sichuan by 3000 B.C. and into Guizhou and Yunnan by 2500 B.C. These southern movements led farther into Taiwan and into Southeast Asia (Zhang & Hung, 2010; Fig. 7). From the lower Yellow River, where rice farming had been well established since 6000 B.C., dispersal routes went northward to the Shandong Peninsula by 3500–3000 B.C., then much later into Korea and finally Japan about 300 B.C. via the Liaodong Peninsula.

Conclusion

Rice in China is more than a staple food. Hundreds of recipes make use of rice for worship at special events, enjoyment at particular feasts, ceremonies, and daily life. Beyond just the edible seeds, the by-products of rice have multiple functions, such as rice straw for making ropes, sandals, hats, mats, and raincoats. For thousands of

years, Chinese traditions of year cycle and philosophy centered around rice farming, as in the phrase “plowing in spring, weeding in summer, harvesting in autumn, and hoarding in winter.” Rice has raised generations of people, and it supported the development of countless perspectives of Chinese culture, such as the living landscape, scientific inventions, transportation systems, astronomical knowledge, supernatural beliefs and religions, and lifestyle that characterize the foundations of Chinese civilization.

Rice in India

Uma Ahuja¹ and Subhash Chander Ahuja²

¹College of Agriculture, CCS Haryana Agricultural University, Kaithal, Haryana, India

²Rice Research Station, CCS Haryana Agricultural University, Kaithal, Haryana, India

Rice, a member of the grass family, feeds two thirds of the human population. Rice is decisively an Asian crop. 90 % of world yields are grown and consumed in monsoonal Asia (East and South East Asia) where rice is the staple because of its ability to tolerate excessive water conditions, both cold and warm climates. Maize and wheat fail to do so. It has adjusted itself to cool, dry land conditions and saline, alkaline, and acid sulfate soils. It has earned epithets as “grain of life” and “rice is life.”

Debates over the origin and domestication of the rice plant continue and will perhaps never be known as the crop is ancient. Archaeological and molecular studies still fail to give an exact picture.

Vavilov in 1908 considered India as the place of origin of rice on the basis of the wealth of rice varieties in the southwest of the Himalayas (Framji, 1977). Of the 150,000 estimated rice varieties of the world, more than 50,000 occur in India (Rani & Krishnaiah, 2001). On the basis of the pantropical distribution of 20 wild species of *Oryza*, Chang (1976) proposed that rice

originated in the early cretaceous period before the Gondwana breakup. This view has found support from recent discoveries at Pisdura, Maharashtra. Plant remains found in the dung of dinosaurs in Pisdura, Chandrapur district, in Maharashtra revealed that dinosaurs ate this grain much before humans. It may give a new turn to the controversy. This pushes the origin of rice 35 million years back during the late Cretaceous period and raises the possibility of rice having an Indian parent. Until now, it was believed that rice originated about 30 million years ago in China (Pallavi, 2011).

Early rice cultivation followed two pathways toward domestication in India and China, with selection for domestication traits in early Yangtze *japonica* and a nondomestication feedback system inferred for proto-*indica*. The protracted domestication process finished around 6,500–6,000 years ago in China and about two millennia later in India, when hybridization with Chinese rice took place (Fuller, 2011).

Genus *Oryza* has only two cultivated species, *Oryza sativa* Linn (Asian cultivated species) and *Oryza glaberrima* Steud (confined to West Africa). *Oryza sativa* is grown on every continent throughout the world, with the exception of Antarctica. Domestication of Asian rice, *O. sativa*, diversified to form two ecological major subspecies groups, *Indica* and *Japonica*. Other studies indicated that the two groups were derived independently from the domestication of two divergent wild rices in China and India, respectively (Second, 1982, 1986), or from three different populations of *O. nivara* (wild rice) existed then in different regions. The hill rices of southeast India, the japonica-like types of southwest China, and the hill rices of Indo-China are said to have directly evolved from the annual wild species in their respective regions. The *aus* ecotype of West Bengal seems to have directly evolved from the upland rices of southeast India, whereas *aman* type came from the introgression of *rufipogon* genes into *aus* type somewhere in the lower Gangetic Valley. The *sali* type of Assam possibly evolved from the introgression of *O. rufipogon* genes into *japonica*-like type somewhere in the Brahmaputra Valley (Sharma, Dhua, Agrawal, et al., 2000).

Rice is grown in almost all the states of India, covering more than 30 % of the total cultivated area. Rice extends from 8 °C to 35°N latitude, from sea level in river deltas, in areas below sea levels in Kerala, 4–6 m deep water in Assam and West Bengal, and at altitude (in meters) of 900–1,500 and even more in Kashmir and on slopes of Coorg (700–900) and Assam (600) (Framji, 1977).

Rice is grown under varied ecosystems on a variety of soils under varying climatic conditions. The climatic factors affecting the cultivation of rice are rainfall, day length, and temperature. Soils capable of holding water for a longer period such as heavy neutral soils (clay, clay loam, and loamy) are most suited for its cultivation. The most important groups of soils for successful rice cultivation include alluvial soils, red soils, laterite soils, and black soils. It is grown normally in soils with pH ranging from 5 to 8. Because of its better adaptation, it is also grown under extreme soil conditions such as the acid peaty soils of Kerala (pH 3) and highly alkaline soils (pH 10) of Punjab, Haryana, and Uttar Pradesh (Tripathi, Govila, Warriar, & Ahuja, 2011).

Rice Ecosystems

No other country in the world has such diversity in rice ecosystems than India with four distinct types of ecosystems: irrigated, rainfed lowland, rainfed upland, and flood prone. More than half of the rice area (55 %) is rainfed, and 80 % of the rainfed rice areas are in eastern India, making its cultivation vulnerable to the vagaries of monsoons (Tripathi et al., 2011).

- (i) **Irrigated ecosystem:** Irrigated rice is grown in bunded (embanked), paddy fields; this accounts for approx. 50 % of the total rice area in the country.
- (ii) **Rainfed upland:** Upland rice fields are generally dry, unbunded, and directly seeded. Land utilized in upland rice production can be low lying, drought prone, rolling, or steep sloping.

- (iii) **Rainfed lowland:** Farmers in the rainfed lowland are typically challenged by poor soil quality, drought/flood conditions, and erratic yields. This area accounts for approx. 32 % of the total area under rice.
- (iv) **Flood prone:** These areas are characterized by periods of extreme flooding and drought. Yields are low and variable. Flooding occurs during the wet season from June to November, and rice varieties are chosen for their level of tolerance to submersion.

Diverse ecological situations in areas of rice cultivation have given rise to the following major eco-specific rice varieties with specificity for season, situation, and system.

- **The aus group:** Early maturing, photoinensitive types can be grown across the seasons except in the winter.
- **The aman group:** Late types mostly photoperiod sensitive and flower during specific time regardless of when they are sown or transplanted.
- **The boro group:** Perform best as a summer crop. When sown during winter, they tolerate cold temperature in the early vegetative stage better than the other groups.
- **The gora group:** Only in short duration, it can withstand a certain degree of moisture stress during its growing period.
- **The basmati group:** Specific to regions in the northern parts of Indian subcontinent, possessing extremely valuable quality traits like elongation, aroma, and flavor.
- Aromatic rices other than basmati are found in different states of the country.

Diverse management systems for rice cultivation are practiced in each of the ecosystems. However, the management of irrigated rice is most diverse. Most rice cultivation is done through transplanting manually, and the use of machines is low. Weeding is done by herbicides and manually. Harvesting is done manually or by machine. In the rainfed lowland, rice is primarily transplanted, and weed control and harvesting are done manually as is threshing through small

threshers. Upland rice is generally broadcast sown on dry soil or dribbled in slash and burn situations. It is harvested and threshed manually. Deepwater rice is broadcast, sown in dry soil with very little weeding as most of the weeds do not survive in deep water. Harvesting and threshing is done mostly manually (Khush, 2005).

Like its cultivators, rice comes in different shapes, sizes, colors, qualities, and tastes. Rice is eaten only after processing (shelling of husk). It is eaten as white rice or parboiled (steamed rice). Rice grains are long, short, medium, thin, or plump. The colors vary from white to black with shades of beige, bronze, russet, purple, and red. People in different parts of India differ in their preference for long or small, glutinous, or nonglutinous, white (raw) or parboiled rice, and scented fine or coarse grained rice.

Discussion on rice cultivation in India would be incomplete without reference to specialty rices. These include colored, aromatic, soft, and wild varieties. Of these, red and aromatic rices are important in India. Colored rice has been preferred in the past for its special features such as medicinal value and exclusive taste. Black rices were the favorites of the royals of China. Red rices are preferred by people in many parts of India, Sri Lanka, and Bhutan. Red rices in Chhattisgarh and Jharkhand of *Bhama*, *Danigora*, *Karhani*, *Kalmdani*, *Ramdi*, *Muru*, *Hindmauri*, and *Punaigora* varieties are more nutritious, and their consumption provides enough energy for whole day's work without feeling hungry (Rahman, Sharma, Sahai, et al., 2006). People in Maharashtra during *Hal Shashti* and *Rishi Panchami* rituals abstain from taking food grown with the help of animals and take wild rice (*Oryza nivara*) and other self-grown plants. Brahmins and tribals eat wild rice during fast days (Ahuja, et al. 2001, 2007; Watt, 1891; Vaughan, 1994).

Before the advent of high yielding varieties, about 300 scented varieties exclusive to their respective areas were grown for the rich and noble classes. Of the various scented rices, basmati of Haryana and Punjab; *Ambemohar* of Maharashtra; *Dubraj* of Madhya Pradesh; *Joha* rices of Assam; *Kamod* of Gujarat; *Badshahbhog*

and *Radhunipagla* of Bengal; *Katrini* of Uttar Pradesh; *Kalanamak* of Uttar Pradesh, Bihar, and Nepal; *Jeera samba* of Tamil Nadu; *Gandhasambha* of Kerala; *Kalajira* and *Badshahbhog* of Orissa; and *Chakhao* rices of Manipur are some that are more well known. Basmati rice surpasses all in its size, shape, grain size, exquisite aroma, cooking quality, and taste which has made it the prince of rices (Ahuja, Ahuja, Thakrar, Shobha Rani, et al., 2008).

The rice crop provides a number of by-products such as straw, husk, bran, and broken rice. Part of the straw is used in preparing cardboard and paper for newsprint, in addition to its traditional use for thatching, grain storage structures, packing material, and religion (Hamilton, 2003; Ahuja, et al. 2013). The husk constitutes the largest by-product and one fifth of the paddy by weight. It has a considerable fuel value and is widely used as boiler fuel in the industry. Rice husks are also a rich source of silica. Rice bran is the most valuable by-product of the rice milling industry. It is obtained from the outer layers of the brown rice during milling. Rice bran consists of pericarp, aleurone layer, germ, and a part of endosperm. Rice bran is utilized in various ways as cooking oil, cosmetics, feed, and fertilizers. Rice bran oil is considered one of the healthiest oils for human consumption. Two interesting uses of rice mentioned in *Jatakas* and *Garud Puran* are the use of sour rice gruel in preparation of arrows and that of boiled rice in cleaning and perforating pearls (Kumar, 1988).

Rice is also converted into a number of alcoholic beverages, known to have medicinal value and to increase palatability in addition to their use as gifts and in personal, social and religious ceremonies (Ahuja, Thakrar, Ahuja, et al. 2001).

In addition to being the basic food of millions, rice is attributed with many medicinal uses. Rice meets most of the requirements of a good and healthy food. This is the only cereal eaten as a whole grain, which according to Ayurvedic texts is more easily digestible than flour (Ahuja, Uma, Ahuja, Thakrar, Rashmi, & Singh, 2008). The French traveler and diamond merchant who visited India in 1646 observed that wheat-eating people had more strength while rice eaters (red rices)

had more stamina (Ahuja, Uma, Ahuja, Thakrar, Rashmi, & Singh, 2008; Vir, Singh, & Tomar, 2005). The editor of the *Rice Journal* in 1938 recorded similar observations on sturdy Japanese and Chinese races and speculated, “May be our people would have better health and more energy if they ate more rice” (Anonymous, 1997). Rice is the main constituent of the life-saving oral rehydration solution (ORS). Ancient Ayurvedic treatises laud the *Raktasali* red rice as a nutritive food and medicine. The medicinal value of shashtika, Sali, and parched rice was documented in *Carakasamhitā* (c. 700 BC) and the *Suśrutasaṃhitā* (400 BC), in the treatment of various ailments such as diarrhea, vomiting, fever, hemorrhage, chest pain, wounds, and burns. Even today, certain varieties are used to treat skin diseases, blood pressure, fever, paralysis, rheumatism, and leucorrhea, as well as being used as a tonic for lactation. The famous *Nivara* rice of Kerala is widely employed in Ayurvedic practice as a body-enriching item, to exclude toxins and delay premature aging. Colored rice (black and red) is rich in minerals (iron and zinc) and polyphenols and possesses antioxidant properties. Traditional varieties such as basmati have a low glycemic index and are useful in weight-reducing diets. Rice-based ORS is known to be better than glucose-based ORS and has been included in World Health Organization recommendations (Ahuja, Uma, Ahuja, Thakrar, Rashmi, & Singh, 2008).

Rice in Indian Folklore

The ubiquity of rice is evident in all forms of folklore, myths, legends, stories, and folktales (Ahuja & Ahuja, 2010). However, its position in Indian folklore is unmatched elsewhere. Its perpetuity is evident in a mélange of ancient texts, proverbs, poetry, and sayings.

There are special transplanting songs in most Indian languages. *Romani* songs of Himachal Pradesh and *Ropani* songs of Bengal are quite interesting. Rice has a respectable place in riddles and proverbs of many Indian languages:

“Flattened rice, fried rice: but nothing like Boiled rice: mother paternal, mother maternal, but none like one’s own mother.” (a Bangla

proverb, Bhattacharyya, 1978) “No charity is greater than feeding the hungry stomachs with rice. It is surest way of getting the blessings from angels.” (a Malayalam proverb) (Ahuja, et al., 1997).

Surnames of some powerful Japanese are derived from rice such as Toyota, Honda, Nakasone, Sawada, Tanaka, and Narita (Huggan, 1995). Names of some important states and countries are based on rice, i.e., Nellore in South India (town of rice), Java, Sikkim, and Japan. Even names of many rites/ceremonies owe their names to this tiny grain as *Dhanpan*, *Bhat*, and *Tilchauli* (Ahuja & Ahuja, 2010; Ahuja, et al., 1997).

Fairs, Festivals, and Rituals Associated With Rice Cultivation

Many Asian festivals are tied to the agricultural cycle, and in many cultures, months are named according to the activity of the rice field. New Year starts with either the sowing or harvesting of rice. Cultivation of rice is hard work and must be carried out at the correct time for sowing, transplanting, weeding, and harvesting. To follow a strict timetable, people became accustomed to working in groups, leading to celebrations in the form of festivals and ceremonies at all crop growth stages, turning the hard job of rice production into joyous affairs. Thirteen festivals associated with rice cultivation are celebrated in Orissa in the span of a year (Ahuja & Ahuja, 2006, 2010; Ahuja, Thakrar, Ahuja, et al., 2000).

Rice and Religion

In India, rice is considered to have divine origin and is considered sacred. The religion is based on a feeling of fear of natural calamities, beyond the control of human beings. People worship nature gods such as Sun, Moon, and Mother Earth and their own ancestors to save themselves from their wrath and to get blessings by animal sacrifices. The ancient scripture forbade this act of cruelty toward animals and replaced it with an offering of rice.

Rice Goddesses

A panoply of rice deities and goddesses is found in Hindu India. *Annapurna* is pan-Indian deity for rice whose shrines are located in Varanasi in the north and Nellore in the south. Lakshmi, the goddess of all crops, is associated with rice, as in the preindustrial period, grain was the symbol of wealth and prosperity (Hamilton, 2003).

In India, even in areas where rice is not the mainstay of people, it is rice which is used in ritualistic observances (Hanchett, 1988). Rice is indispensable in many festivals for rituals both religious and otherwise. Farmers in Indonesia offer rice to the rain god to ensure favorable weather and a good crop, while the Chinese offer rice cakes to the monster god at the lunar New Year. Rice cakes are considered a symbol of prosperity. India is a country of traditions and an amalgamation of Vedic and tribal cultures and home to innumerable gods and goddesses. Worship and vrats are observed for family welfare and for fulfilling wishes or desires. Rice forms part of all these worships, vows, and festivals. Every religious ceremony in India starts with *tilak* (a mark made on forehead) with *akshat* (undamaged, washed rice). No religious ceremony is considered complete in the absence of *Akshat* or rice in some form.

Rice in Rites de Passages (Sanskara): In all traditional societies, the transition of life is observed and celebrated with ancient rites that predate written history. Rice is associated with the various rites of life in India, Indonesia, China, Malaysia, Thailand, Korea, and Japan. In Hindu ceremonies, rice is an emblem of purity, fertility, and prosperity and is thrown into the sacred fire during wedding ceremonies. Rice is an indispensable item and a figure in all rites of life, be it birth, marriage, death, or post death ceremonies.

Marriage is the most important event in anybody's life. In India, turmeric rice forms an integral part of the marriage invitation. The engagement ceremony is initiated with *tilak* of turmeric rice. The marriage ceremony starts with tying amulet-containing turmeric rice and ends

with a blessing of showering rice. The custom of welcoming a person by showering rice grains can be traced back to this ritual. It may be that the Western custom of showering rice during wedding ceremonies comes from the Hindu tradition. A *Kodava* marriage in Coorg offers a view of the extent of the use of rice in marriage rites. At least 13 times rice grains are used to complete the rites of various steps of a *Kodva* marriage (Ponnappa, 1986).

In most Asian countries, the concept of rebirth after death has evolved into elaborate ceremonies at death and after death to pay respect to the deceased person.

The deceased person is separated from the living, and the corpse must be separated from its spirit. Rites in death also involve much use of rice in different forms. Tribes in Assam, Orissa, Manipur, and Nagaland use rice beer and cooked rice in funeral rites. In South India, in the event of death of any person away from home, a mock cremation is conducted with bones and ashes. A replica of the figure is made with 360 *palas* leaves [*Butea monosperma* (Lamk.) Taubert, fire of jungle] over a black antelope skull, with 32 pomegranate seeds for teeth, and the people sprinkle rice grains over the figure. Then cremation is done (Crooke, 1896).

Forms of Rice Used

Ceremonial use of rice in various rituals in India is not of recent origin but dates back to the Vedic period (in ancient texts). Rice is offered as oblation to God, deities, village deity, and religious ceremonies; as alms to Brahmans and needy persons; and as part of festivals in different forms. An offering of unhusked rice (paddy); white unbroken grains, colored yellow (vermilion/turmeric), sun dried, cooked, fried, parched, and popped; rice flour; and rice beverages. Another form of rice used in religious ceremonies and tradition is rice flour and its paste. The paste forms part of the makeup of Kathakali performer in Kerala and also in making the ritual diagrams on the floor and walls.

Women create patterns using rice flour paste, wheat or barley flour, and rice powder mixed with turmeric, cow dung, and soil. Rice flour used in these designs becomes food for ants, insects, and birds. These are symbols that welcome the new bride and announce a marriage or a birth. These are also drawn on all ceremonies related to rites of passage from birth to death or after death *shraad* ceremony. Warlis of Bombay draw circular patterns with rice paste on the occasions of funerals and marriages. Likewise, *Sanja* wall motifs (drawn with rice paste and grain) of Madhya Pradesh, Rajasthan, Haryana, and Uttar Pradesh are drawn at the *Sharad* month to appease the ancestors. The tribal people offer rice beverages in order to propitiate the deities and use it in various ceremonial purposes, in rites of passage, and in rituals at various stages of the rice crop. Peasant Hindus do not employ rice beer (or fermented grain in general) in rituals.

Ceremonial rice use is not physical only but has symbolic values, too. Fried rice is a symbol of fertility. Hanchett (1988) identified the importance of rice in religious and social ceremonies in Karnataka and pointed out that other food items were used in rituals and rites and as offerings to God. Rice is a major symbolic element in ritual practices as food, as decorative item, or as object of play and medium of communication. Rice functions as a key symbol for Hindu culture. Its various cooked forms provide aesthetic guides and models for interpretations of life – birth, growth, maturation, and interrelationship – and even death and after death. Rice offering stands as a symbol for perceiving existence, consciousness, and experience in all things. Gupta (1991) explains, “Rice being one of the earliest cereals known to man, it started being associated with food and is often considered to be the creator. Rice being held sacred it is used in all religious ceremonies.”

Huggan (1995) says, “Rice is the mainstay of major population involved in its production. The loss of a rice crop can result in major human catastrophe.” In Asia, life starts with rice and ends with rice. Rice to an Iban farmer is life and

ancestor; to traditional Japanese, it means cool spirit; and to a Javanese, it is more than life and God (Ahuja & Ahuja, 2010).

The relation of rice, religion, and tradition is complementary; religion assures the conservation of rice varieties through its repetitive use in ceremonies, rites, and rituals.

Rice in Korea

Hahnee Hahm
Chonbuk National University, Jeollabuk-do,
South Korea

Geography

Korea is a mountainous country, consisting of high mountains, hills, and valleys. Extended plains can be found on the western side of the Korean peninsula, where major rivers meet the West Sea. From the north to the south, Anju Bakcheon plains developed around the estuary of Cheongcheon river, Pyeongyang plains in the Daedong river, Jaeryeong plains in the Jaeryeong river, Yeonbaek plains between the Jaeryeong and Yeseong rivers, Gimpo plains in the Han river, Pyeongtaek plains in the Anseong river, Nonsan plains in the Geum river, Honam plains between Mangyeong and Dongjin rivers, Naju plains in Yeoungsan river, and Gimhae plains in the Nakdong river.

History

Rice planting in Korea can be traced back to 1000 or 2000 B.C. Archaeological evidence shows that people living on the Korean peninsula started to plant rice from the later period of the Neolithic Age or the early Bronze Age (National Museum of Korea [NMK], 2000, p. 11). In recent years, newly excavated archaeological evidence such as carbonized rice has reignited the discussions among archaeologists with respect to the origins of rice. Recent developments in scientific measurements have helped to determine the date of

plant opal, going back to even a. 3000 B.C. Carbonized rice and Neolithic tools such as stone hoes, plow shares, saddle quern, grinding stone, and pestles show that the ancient people lived in the areas where those archaeological items were found, cultivating grains such as rice, bean, millet, and other grains. The more precise date and place of the origin of rice is still debatable and open to more in-depth discussion. There are two different positions: one is the Chinese origin theory which has been widely accepted in the Korean archaeological scholarship, and the other is a new wild rice theory which is supported by the recently excavated plant opal showing the existence of wild rice that can be traced back to around 3000 B.C. (Ahn, Seung Mo, 1993, 1999; Lee, Ho Chol, 2004; NMK, 2000; Park, Tae Shik & Lee Yung Jo, 2004; Yim, Hyo Jae, 2001).

By the mid-Bronze age, rice cultivation was widespread on the Korean peninsula. Carbonized rice and pottery jars engraved by rice marks can be traced backed to the eighth to the seventh century B.C. The potter jars and the various farming tools which have been excavated evidence the cultivation of rice in the paddy. The carbonized rice has been found in many different locations in southern regions of the Korean peninsula, including Gangreung, Jinju, Sancheong, Yeosu, etc. (NMK, 2000).

Around this period, rice-farming communities began to form. Collective labor was crucial to rice farming. People came to live together and form social institutions in order to work together. After a while, such communities which were initially based on egalitarianism became stratified by power, leadership, and surplus production. In particular, since water control was significant for rice cultivation, those who could achieve efficient access to water were able to situate themselves as a ruling class. This eventually led to the establishment of a stratified political organization, chiefdom, or state (Kim, Bum Chul, 2005).

Farmers in Korea began to use iron tools for rice cultivation a. second to first century B.C. More importantly, historical records show that large-scale hydraulic facilities were constructed during this period. By the third

century A.D., people were able to control water by constructing dams and reservoirs. Sometimes, new paddies were created by building dikes along the river (NMK, 2000).

In around the fourth to fifth centuries A.D., rice production increased due to two different but closely related developments: the development and spread of iron farming tools such as rakes, shovels, axes, iron spades, and sickles on the one hand and the increase of farming populations who could use such iron tools on the other. For example, iron spades which were used for pulling and distributing water onto the paddies were found on the Korean peninsula around the fifth century A.D. but not in China or Japan during the same period. The use of these iron spades evidence the utilization of high technology in rice cultivation with irrigation systems (NMK, 2000).

There was a great increase in rice production as a result of the advancement of iron farming tools and the use of the cow to plow paddies. According to the old historical book called *Samguksagi* or the *History of the Three Kingdoms Period*, in the reign of King Jinjeung (502 AD) cow plowing was encouraged by the state (NMK, 2000, p. 84). In addition, many irrigation facilities were constructed around the sixth century. The detailed records about dam construction were found in several significant monuments erected around that period: Cheongje Monument in Yeongcheon and Musul Ojak Monument erected in 561. These records indicate that the irrigation facilities made it possible to enlarge paddy lands and increase rice production. Also as a result, farmers of that period were able to cultivate various grains both in paddies and dry fields (NMK, p. 85).

Irrigation systems were efficiently controlled by the state. The construction of many dams, dikes, and reservoirs were under the control of the central and local governments. Gradually, more and more local governments took over the establishment of irrigation systems such as constructing smaller-sized dikes and dams.

During the Choson Dynasty (1492–1910), advancements in rice farming consisted of the development of a systematic agricultural policy

and growing scientific research on rice. Many books related to agriculture written by renowned scholars were published. One of the noticeable developments in rice farming in the later Choson period was the introduction of transplanting and two-cropping. Farming tools were also developed in order to adapt to each region's soil and geographic features. Hundred and ninety-one different tools were recorded in the tool book written in the later Choson period. But records indicate that there were only about 40 different kinds of tools in the earlier Choson period (NMK, 2000).

During the Japanese colonial period (1919–1945), modern farming technology was implemented mostly by Japanese landlords and the colonial government. The main purpose of the implementation was to increase rice production. Many agricultural development policies were implemented including the introduction of new varieties of rice, utilization of fertilizers, construction of new dams and dikes, establishment of irrigation cooperatives, land reclamation in wasteland, seashore, estuaries, etc. Because of these developments, agricultural lands expanded from 1,320,000 *chongbo* (area unit used in Korea, 1 *chongbo* = 1 ha) in 1920, the very year of annexation, to 1,640,000 *chongbo* by 1941. Rice production had a corresponding increase from 12,400,000 *sok* (volume unit used in Korea, 1 *sok* = 180 l) in the 1910s to 25,000,000 *sok* in the 1940s. The production rate per are almost doubled from 0.77 *sok* per 10 are in the 1910s to 1.5 *sok* per are in the 1940s. However, the increase in rice production was outpaced by the increase in rice exports to Japan (NMK, 2000).

During the postliberation period (1945–1953), which was marked by chronic political instability, rice production in the Korean peninsula dropped to about 1.2 *sok* per are. The postcolonial government tried to rejuvenate rice production through various political means. One of the major problems faced by the government was a high tenancy rate which led to social and political clashes between wealthy landlords and poor tenants. The government forced land reform by implementing a return-land-to-cultivator policy in 1948. This reform contributed considerably to the establishment of a majority of petty

landowners who grew rice for themselves on their own land. Though much criticism has been levied toward the postcolonial land reform, evidence indicates that the reform turned out to be a successful farm policy overall.

Green Revolution in Korea

During President Park Cheong Hi's regime (1961–1979), a series of state-run economic development projects were implemented with vigorous enthusiasm. Because of chronic rice shortage faced by Koreans during the 1950s–1960s, there was an urgent emphasis by the state on increasing rice production. Dam constructions, repairs of old irrigation facilities, rearrangements of paddies, and expansions of arable land through reclamations were undertaken throughout the entirety of South Korea. New varieties of rice such as *jaegeon* (revival), *jinheung* (progress), *sinpung* (new wind), and *hogwang* (bright light) were bred. The yields associated with some of the new varieties, such as *tongil byeo* (reunification, IR667) among others, were successful in that the yield was double or triple of the yields associated with old varieties. Most farm households planted *tongil byeo* in the 1970s. It is interesting to note that the names of new varieties implied development, progress, and innovation. By building large-scale fertilizer plants, it was possible to increase production of chemical fertilizers in order to distribute widely to farm households. Government subsidies also provided financial support to cultivators for the purchase of weedkillers, pesticides, and insecticides. The state-driven rice production increase contributed greatly to the easing of food shortages and the stabilization of rice supply to consumers. The mechanization in agriculture also reinforced the increase in yield with a decrease in labor. In the past, rice cultivation was a very labor-intensive agricultural practice, but presently, the entire process, from transplanting to harvest, has been completely mechanized.

Total rice production in South Korea increased from 3,920,000 t in 1966 to

5,210,000 t in 1976. The production rate also greatly increased from 287 kg to 429/508 kg per 10 are (NMK, 2000, p. 196; Statistics Korea, www.index.go.kr). The green revolution that South Korea achieved in the 1960s–1970s is attributable to the strenuous efforts by all stakeholders, including policymakers, administrators, researchers, and cultivators.

Industrialization and Rice

Since the 1980s, the decreases in acreage of paddies and the farming population have been prominent (Figs. 1 and 2). Industrialization and urbanization have continuously shrunk the agricultural economy, which had always been the backbone of the nation. In addition, the eating habits of Koreans have gradually changed to result in a substantial reduction in rice consumption.

There is another factor threatening rice farming in Korea. Global market pressures have made their mark on South Korea's protectionist policy regarding rice farming. Korean farmers and their supporters insist that rice is important for Koreans not only as a staple grain but also because of an emotional attachment. Their position is that given the special status of rice within the Korean culture, Korean rice farming must be protected from global market competitions. Admitting the national sentiment or cultural nationalism, South Korean government has so far kept rice out of the Free Trade Agreement (FTA). However, such protectionist policies are due to run out. In 1994, the South Korean government made an agreement on rice import quotas with the World Trade Organization with a 20 year term. With the expiration of this agreement in 2015, South Korea will be opening its rice to the global market.

From the 1960s to 2005, the South Korean government purchased rice directly from producers after the harvest. The purchase price was negotiated between the government and farmers. As the government's protectionist policies come to an end due to the pressures of the global market, the government has set up an alternative

strategy in order to mitigate negative impact on South Korean farmers. The government is purchasing rice for storage in public granaries and thus protecting the rice farmers from the ups and downs of supply and demand in rice. It is an important and necessary measure, according to the government, to strengthen food safety.

At present, import of rice from China, USA, Thailand, and Australia is increasing. The imported rice makes up 8 % of total rice production. Most imported rice is sent out to North Korea and other developing countries but is also consumed domestically (Statistics Korea, www.index.go.kr) (Fig. 3).

How to Grow Rice in Korea?

The preparation for rice cultivation starts in early spring, February or March. Farmers have always observed a farming schedule based on the 24 seasonal divisions, which originates from an old Chinese system. A year is divided into 24 seasons measured by the ecliptic longitude so that the 24 seasonal divisions for farming are congruent with the solar calendar. Given the fact that the lunar calendar was widely used in the past for everyday life, farming schedules were carefully set using celestial science (Table 1).

Culture of Rice: Different Entities and Meanings of Rice

In the minds of Koreans, rice does not exist as a single object. Rice is simplified in the Western way of classification. In comparison to the Western thought of rice as a single entity, in Korean thought, there are three to four different identities within the single physical concept of rice, and each identity delineates a different function and meaning for the general concept of rice. Koreans are confused by the Western way of classification of rice as a single object. Koreans have developed their own way of epistemology of rice based on its long history of agricultural livelihood (Hahm, Hanhee, 2005).

Rice in Korea,

Fig. 1 Plains and rivers in Korea (Source: Korea Digimap <http://koreadigimap.co.kr>)

The English term, *rice*, has four different terms and meanings in Korean; *mo* is a very young stage of the rice plant; *byeo* means its later stage and is distinguished from *mo*; *ssal* means hulled grain; and *bap* means cooked rice.

This linguistic difference between English and Korean is also directly related to the fact that speakers of each language understand the object (s) in a different way. Unlike in English, the articulations of rice in Korean have been

Rice in Korea, Fig. 2 Area of paddy, 1951–2012

year	Area of Paddy (unit: ha)

meticulously developed to describe rice in terms of growing, producing, and cooking.

The Stage of *Mo*

Farmers begin to prepare for rice farming in the early spring. They nurture seedlings from the seeds and plant them in the seedbed during April and early May. The seedlings are called *mo*, and the seedbed is *mop'an* (Picture 1). After waiting for about a month while *mo* grows in the seedbed, farmers transplant the baby *mo* to the rice fields in May and early June. Traditionally,

transplanting was the most difficult farm job. It required intensive labor in a short time period. Group work or cooperation among neighbors was indispensable to the completion of this task, and therefore, before the mechanization of the Korean agriculture industry, farmers established various forms of labor cooperatives such as communal work and labor exchange institutions in order to cope with the large amount of work necessary for transplanting (Pictures 2 and 3).

After transplanting, *mo* grows quickly in fields filled with water. *Mo* grows into *byeo* under the summer heat. Once the plant grows large enough to cover the field, farmers call it *byeo*. In the early

	<i>daehan</i> [very cold days]	Jan. 21	

fall, *byeo* starts to ripen. In July, *byeo* develops ears of rice. At the end of the summer, *byeo*'s head bows as the ears of rice get heavier. An ear of rice is called *isak*, and the plant whose ears get heavier is called *isak paenda*. The ripeness of ears of rice alerts the farmers to harvest time. Farmers are ready to harvest in the early fall (Pictures 4 and 5).

Byeo Seen as Heaven's Offering

It takes 6–7 months for the sprouting *mo* to transform into the harvest *byeo*, depending upon the natural environment. *Mo* and *byeo* are different stages of the rice plant. They are natural resources that the farmers believe belong to Nature,

Rice in Korea, Picture 1 *Mopan* around the end of May

Rice in Korea, Picture 2 Transplanting in June

Heaven, or an agricultural god regardless of who physically owns the plants. According to farmers' understanding of cosmology, the farmers are responsible for the rice plants and must take care of them, but the eventual success of a

farming season and a good harvest is always in the hands of supernatural forces. The farmers must ask help from these gods every step of the way. Every year, from the first day of New Year to the completion of the harvest, farmers dedicate

Rice in Korea, Picture 3

Mo is growing in paddy in July

**Rice in Korea, Picture 4** *Byeo* is ripening in September

various religious rituals to god(s) with sumptuous food sacrifices.

Because of the farmers' beliefs that *mo* and *byeon* are provided by the god(s), the farmers are open to collectively caring for *mo* and *byeon*. They share labor, tools, farming animals, and information. This system of cooperation for planting and growing *mo* and *byeon* is the traditional norm. The

farmers who grow *mo* and *byeon* consider themselves to be legitimate cultivators acknowledged by Heaven. There is a Korean classic expression, "Farmers are the foundation of the world (*nongja chonha ji daebon*)."

They are expected to cooperate with each other, be humble so as to hear the voice of Nature, follow the rules of the agricultural god, and wait until Heaven's orders. During

Rice in Korea, Picture 5 Harvesting season

the *mo* and *byeo* planting season, farming villages are filled with the spirit of cooperation, modest sense of living, and spirituality. In fact, at each stage of the rice season, farmers used to regularly practice worships for Heaven and gods who are in charge of rain, land, and agriculture and all other gods related to farming. These religious rituals are accompanied by village festivals.

In order to grow *mo* and *byeo*, farmers form various work units. The smallest work unit is a family, and a larger unit is made up of neighbors. The largest team is the village communal work team which comes together for the transplanting season regularly each year and also on special occasions for the construction or repairs of reservoirs and water routes. The village work team helps poor families that do not have enough labor resources to independently farm. The elderly, widows, and sick people benefit from the village cooperative work team.

***Ssal* as Commodity**

In the fall, farmers are busy harvesting the fully matured *byeo* with heavy ears. When a field

becomes covered by the fully grown golden *byeo*, Koreans call it the golden rice field. The term has double meaning. The golden color implies a good harvest and farmers' happiness as a result. Gold also implies money and wealth. In the agricultural economy, rice was used as a monetary exchange unit. Once *byeo* turns gold, its character changes as well as its color and shape. Unlike immature *byeo*, the golden *byeo* is ready to become a commodity. Matured *byeo* is thrashed and yields *ssal*, the husked rice. After *ssal* comes out of *byeo*, it no longer belongs to the realm of Nature and Heaven but belongs to the owners of the rice field. It means that *ssal* is a commodity and becomes enmeshed in the Korean political economy (Picture 6).

Summary

English speakers do not differentiate between *ssal*, *byeo*, and *mo*, which are three different objects for Koreans. Koreans have heightened awareness of the differences in the rice plant in each growing period. The rice plant has a different identity, as well as a different name, for each

Rice in Korea, Picture 6 *Ssal*

period of its development. I have analyzed the stages of *mo* and *byeo* together because the two stages have common cultural characteristics. However, *ssal*, unlike *byeo* and *mo*, raises issues of rent payment, tenancy contract, ownership of land, state taxes, market prices, etc. Landowners tried to get more *ssal* out of the land, and the government found ways to collect more taxes on the *ssal*. Historically, *ssal* was an object which was firmly controlled by the wealthy and the powerful in Korea.

As long as *ssal* remains a valuable economic resource, people compete with each other for limited ownership rights. The ruthless competition over a valuable resource creates conflict between the haves and the have-nots. During the Choson Dynasty, there were significant class conflicts between the *yangban* (noblemen) landlords and the peasant cultivators. The angry peasants who were often stripped of their legitimate share of yields by the *yangban* landlords fought against exploitation. Many of the poor peasants at the time did not possess enough land for subsistence so they were forced to rent agricultural land from rich landlords and paid annual rent to the landlords. From the Choson period to the colonial period, rent for agricultural land in Korea was 50–60 % of the total yield. The tenants paid rent with rice, usually in the husked form. Agents of the landlords collected rent on the spot at the harvest.

In the industrialized South Korea, farmers consist of less than 6 % of the South Korean population, and the agricultural economy constitutes 2.3 % of the nation's GDP as of 2011 (The Korea National Statistical Office, <http://kosis.nso.go.kr>; Han, Jang, Cho, & Park, 2011). Contrary to the numerical representation of agriculture in such economic indices, however, rice still retains an exceptional position in the mind and thought of Koreans. They have special cultural attitudes and historical memories of rice which have contributed to continued importance of rice in Korea despite evidence of decreased consumption.

First, Koreans are proud of the history of rice planting in their country. Evidence indicates that Korea was using advanced irrigation technology and facilities even in the early historical periods.

Second, the long history of rice cultivation has been embedded into the day-to-day culture of Koreans. From eating habits to religious beliefs, Korean culture cannot be understood without an understanding of the rice culture.

Third, the political economy of rice has been a scorching issue throughout Korean history. Mainly class conflict between wealthy landlords and poor tenants has been the focal point of social unrest. Antagonism between landlords and tenants often ended with tragic battles in village societies during the Korean War.

Rice has long been the major staple for Koreans. Koreans still prefer to eat rice at every meal. The ordinary Korean meal table, which is the same for breakfast, lunch, and dinner, consists of cooked rice, soup, kimchi, and various side dishes. The westernized lifestyle which has been adopted by many city dwellers allows them to have more options for meals such as bread for breakfast, noodle dishes for lunch, and pizza or meat for dinner. However, a recent survey indicates that 69.3 % of Koreans continue to eat rice for breakfast every day even though preparation for a meal consisting of rice and side dishes is far more inconvenient than preparing a western-style breakfast (Yeon-Seo Mun, Eun-Kyung Jung, Nami Joo, & Ji-Young Yoon, 2011). Another study shows that in contrast, the Japanese and Chinese have changed their eating habits in that

Rice in Korea, Picture 7 Korean table (*habsang*)

they prefer bread to rice at breakfast for the sake of convenience (Ahn, Myeong Su, 1992). Koreans tend to be more conservative in their eating habits than the inhabitants of the other two East Asian countries where rice has historically been the staple grain. Moreover, many South Koreans still believe that rice should be protected from free competition in the global market (Picture 7).

Rice in Taiwan

Y. I. C. Hsing
Taipei, Taiwan

Taiwan is a small country located in Eastern Asia. It is about 161 km away from the southeast part of China and about 483 km north of the Philippines. The exact location is 120°E–122°E and

22°N–25°N. The Tropic of Cancer passes through the center of Taiwan. The south part of Taiwan is considered tropical and the north subtropical. The characters and habitat of the rice in Taiwan are quite unique because (1) there are many high mountains and rice has been grown from sea level to high altitude, (2) rice may be grown from February to November each year, and (3) both japonica and indica rice varieties are cultivated. For thousands of years, people in Taiwan selected several important traits such as insensitivity to photoperiod and semidwarfism that have affected modern rice cultivation in the world.

The arable land in Taiwan is about 803 kilohectares, and half of the land consists of paddy fields for rice production. Because the temperature from February to November is suitable for rice growth, rice is grown twice a year. The first cropping season is from February to June and the second from July to November. In the first cropping season, both temperature and day length increase from germination to harvesting and in the second, both decrease. Wild-type rice is a short-day plant in that it flowers when the day length is shorter than the critical day length (usually 14 h). If genes controlling day length sensitivity are not mutated, as in most modern varieties in Japan and Korea, rice could not be grown twice a year. Instead, they would flower and set seed very early, such as about 1 month after germination, or very late, such as more than half a year after germination. In previous times in Taiwan, people selected lines with insensitivity to day length. Thus, rice could be grown in different places at any time of the year as long as the temperature was suitable. Another trait selected in Taiwan that is important for world rice production is semidwarfism. Rice plants with this trait have a strong culm [stem] and are resistant to lodging and thus may improve yield production.

Rice in Taiwan in Ancient Times

Taiwanese aborigines were the original inhabitants of Taiwan. Their ancestors may have been

living on Taiwan and its surrounding islands for approximately 5,000 years before the major Han Chinese immigration began in the seventeenth century. Taiwanese aborigines are Austronesian peoples, with linguistic and genetic ties to other Austronesian ethnic groups such as people of the Philippines, Malaysia, Indonesia, Madagascar, Polynesia, and Oceania. Archeologists recently excavated the remains of several early cultures in Taiwan. The most plentiful plant remains were carbonated rice and foxtail millet grains. The earliest ^{14}C date of these excavation sites is ~5,000 BP. Sequence analysis of early aboriginal Taiwanese rice landraces suggested they were japonica rice. The aborigines first stayed in the plains area; some then moved to mountain areas. Both japonica and indica rice were cultivated in each village. The cultivated practice was basically upland or dry farmland. Several of the accessions consisted of important mutations in genes controlling insensitivity to day length.

Rice in Taiwan in Earlier Times

When Han Chinese moved to Taiwan in the late Ming and early Ching Dynasties, they brought paddy-field rice cultivation practice and tools as well as many indica rice landraces. Rice cultivation has been in paddy fields since then. More than 1,000 indica accessions were grown, all in paddy fields. During that period, many “early” and “semidwarf” lines were selected and fixed. Examples are *Ching-Yu-Tsau* from *Ching-Yu* and *Tsau-Chan* from *Chan* (*Tsau* means early). *Dee-Geo-Woo-Gen* (DGWG) was selected from *Woo-Gen* and *Dee-Geo-Hoe-Le* from *Hoe-Le* (*Dee-Geo* means semidwarf). About 100 years later, these important traits were used worldwide for modern varieties.

Rice in Taiwan During Japanese Colonization (1895 to 1945)

Japanese prefer the taste and texture of japonica rice to indica rice. Early during their colonization, the Japanese tried to improve the existing

indica rice accessions in Taiwan. They selected 175 landraces from the 1,197 accessions and promoted only these races. Later, they tried to grow japonica rice in Taiwan. They brought many Japanese accessions to Taiwan and tried to acclimatize them. The early attempt failed because of the slow growth and low yield. In 1924, two Japanese rice breeders used two Japanese landraces, Kameji and Shinriki, as parental lines for cross-breeding. Five years later, the new variety Taichung 65 was produced. After the first success, many more japonica varieties were bred and cultivated. The rice was more sticky and soft than the normal indica rice and people adapted to the varieties quickly. In 1935, the cultivated area was greater for japonica than indica, with continually increasing area. For 60 years, the major type of rice consumed in Taiwan changed from indica to japonica.

Rice in Taiwan After the WWII

Breeding programs for both japonica and indica rice were emphasized during the 1950–1970s in Taiwan. One well-known indica variety was Taichung Native 1 (TCN1), from the two parental lines DGWG and Tsai-Yuan-Chon. This was the first semidwarf rice variety in the world. The International Rice Research Institute (IRRI) was established near Manila in 1960, and Dr. T. T. Chang, a well-respected Taiwan rice breeder, was invited to move there. He brought several good germplasms, including TCN1 and DGWG, to IRRI. TCN1 was first cultivated in India, and its yield was much higher than the local varieties. Dr. Chang and another IRRI rice breeder, Peter Jennings, worked together and made several crosses. The combination of Peta (landrace from Indonesia) and DGWG had very good agronomic traits; the new variety was designated IR8. This was a semidwarf rice, about 120 cm tall, with a strong stem that held the plant upright even when heavily fertilized. In addition, it was insensitive to day length. IRRI scientists quickly demonstrated that IR8 rice yielded about 5 t/ha with no fertilizer and almost 10 t/ha under optimal conditions. This was

10 times the yield of traditional rice. With the insensitivity to day length, the rice could be grown in many latitudes and at any time of the year. This variety was successful throughout Asia and designated the “miracle rice” in the late 1960s. IR8 played an important role in world agriculture because it fed the fast-expanding world population and was known as the “green revolution” rice. Until current times, DGWG was used in the pedigree of about 90 % of the world’s indica rice breeding programs.

The breeding program for japonica rice during this period emphasized non-lodging, high yield, and resistance to pathogens and insects. Grain quality was not the major goal for breeding purposes. For instance, Tainung 67 was the leading variety, occupying at least 70 % of the cultivated area for 20 years. Although indica rice was still cultivated, most was used for food processing.

Rice Cultivation and Utilization in Current Times

After the economy improved in Taiwan, many changes occurred in rice breeding, cultivation, and utilization. For japonica rice, grain quality became an important factor: good taste, aroma, low chalkiness, and good texture. For indica rice, breeders crossed indica and japonica, and the new varieties had a similar texture to japonica rice, with less amylose content as compared with the indica varieties in Southeastern Asia. Cultivation moved to mechanical farming, so a strong culm was important. Currently, the cultivation area for japonica, indica, and glutinous rice in Taiwan is 87, 8, and 5 %, respectively. Rice is grown in both cropping seasons in about 81 % of the paddy field, about 4 % and 16 % of the field only for the first and second cropping season, respectively. The production is enough for self-consumption, with only a small amount for export.

Rice is also used for food processing. Mainly two types are used: the indica type with high amylose content and glutinous (sticky) rice. The processing involves whole grain, milk/paste, and fermentation. The products of whole-grain rice

include rice rolls, pearl pillion [a dessert], and fried rice. The products of milk/paste rice include rice noodles, rice pudding, rice tube pudding, rice cakes, and rice dumplings. The products of fermentation include rice wine, rice vinegar, and sweet fermented glutinous rice wine.

Rice and Life in Taiwan

Rice has been the major staple food in Taiwan for thousands of years and is very important in Taiwanese culture. For instance, “rice bowl” means job, and “eat soft rice” means jobless. Rice is also used in several village names, such as “Tien-Chun” (between rice field) and “Da-Dau-Chen” (big rice wall). Many bridges were constructed with bricks and rice paste, a mixture of glutinous rice and brown sugar. Rice is also important in religion and ideology. Rice puddings are always used for worship of ancestors or gods. Rice has been combined with the land deity temple in many villages.

Rice Paddy Storage in India

Subhash Chander Ahuja¹ and Uma Ahuja²

¹Rice Research Station, CCS Haryana Agricultural University, Kaithal, Haryana, India

²College of Agriculture, CCS Haryana Agricultural University, Kaithal, Haryana, India

Since ancient times, Indians have realized the importance and need of grain storage in the wake of their seasonal production (one harvest a year), proneness to weather vagaries, and importance as a major food. The Indians developed methods to store grains to ensure household food supplies. Storage of paddy grain, seed, and rice becomes of utmost importance, being the staple diet of two-thirds of the Indian population. Now storage is undertaken at the producer, consumer, trader, and government levels. The bulk of the rice crop is stored as paddy as the grain keeps far better and for a much longer period and it is husked when

required. The method and structure of storage may differ depending upon users' requirements, weather, climate, and level of storage.

Bulk Storage: Government Level

Various kings in India stored grains. Storage structures are mentioned in ancient scriptures such as *R̥gveda* (8000 BC), *Yajurveda* (3000 BC), *Sāmveda*, and *Samhitās* (7000 BC) (*Panini*, 600 BC; Varāhmihira, 505–587 AD) (*Misra*, 1982). These were referred to as *stivi* in *R̥gveda* (Pandey, Dubey, & Pandey, 2000). Grain storage in well-built granaries was described in Kautilya's *Arthaśāstra* (325–296 BC) and Vishwakarma's *Vastuśāstra* (Ahuja et al., 2010).

The remains of grain storage structures of different periods have been found in various sites in India. Granaries evolved from mud to brick platforms and to pit silos. The well-ventilated granaries in Harappa were on a mud platform with corridors between them. In Mohenjo-Daro (2500–1750BC), the granary was built of wood which disappeared and left a massive brick platform with steep sloping sides and blocks arranged crosswise to facilitate air circulation (Pandey et al., 2000). Storage in granaries built later in the Indus Valley (2500–1500 BC) was on a large scale and of a sophistication never matched later in India's history (Achaya, 1998). The granaries in compartments were well ventilated and well built with baked bricks (Wheeler, 1968). Later, granaries excavated at Inamgaon (Maharashtra) of Mid-Chalcolithic (1750–1000 BC) are characterized by pit silos with round mud platforms for keeping storage bins (Dhalvalikar, 1975–76).

During the Buddhist period (c. 500–100 BC), grains after cleaning and sealing in clay pots (*ghadā*) were stored in private- and state-owned stores called *kotār* or *kshtagar* (Jain, 1947). Storage of grains in well-built granaries provided with all necessary amenities for the protection of grains has been described in *Arthaśāstra* of Kautilya (325–296 BC) and *Vastuśāstra* of Vishwakarma (Pandey et al., 2000; Pranjape, 1993; Raychaudhuri & Roy, 1993; Sensarma, 1998).

Producer Level: Estimates reveal that 60–70 % of food grain produced in India is stored for seed as well as for consumption at home in indigenous storage structures. The storage techniques for both differ slightly as seed needs more careful handling. The seeds are stored in pots, boxes, baskets, or bags, while bulk grains are stored in storage structures. The seed is considered an important entity in agriculture since ancient times and references to its collection, preservation, and storage are found in ancient treatises. *Kashyapiyakrishisukti* refers to seed storage as the first duty of a farmer for the prosperity of his house and states that seed storage and its distribution in the proper season is the King's duty (Ahuja et al. 2010).

In the mid-historic period (beginning of Christian era to 1200 A.D.), seeds were stored in receptacles made of straw and leaves with the inside space coated with cow dung. Granaries made of earth, straw, or bamboo, standing on pillars, the upper storey of houses covered with lids coated with cow dung, and further coated with mud all over, closed and sealed with earthen rods, are all referred to in the ancient literature (Jain, 1947).

Various surveys came across different type of traditional storage containers and structures used since the mid-historic period. Indigenous storage practices were fulfilled by indigenous structures designed by farmers themselves with freely available materials at an affordable cost. The selection of a storage system by an ethnic group is related to climate, local natural resources, and customs. Clay provided an impervious coating which would not admit insect pests. Various plants and products used in the top cover and inside had insect deterrent action. Certain practices were unique to a given culture and vary between regions, villages, and even communities.

Storage structures could be indoor or outdoor, temporary or permanent, and underground or aboveground and could be individual or community based in the form of bins, mud houses, bamboo houses, brick houses, or some combination of these. The Rural and Agricultural Glossary of Crooke (1888) offers a number of terms associated with various types of house granaries such

asdhundki, bandā, dālā or korangā, bakhār, bakhārī, bukhārī, chauras, chahrasī, dehrī, kano, khātā, khātla, khāti, kothi, thekī, kuthlā, kotār, kothila, or kothī.

Storage Containers for Seeds

Earthen pots are made up of burnt clay with a capacity of about 5–10 lits and provide a storage time of about 2 years. The pot is topped up with dried leaves of *Pongamia pinnata* (L.) Pierre and *Azadirachta indica* A. Jussieu. These are called *matkā* (Haryana, Rajasthan, HP, Uttar Pradesh, Punjab, Bihar, M P, Jharkhand), *Kulukkai, sal* (Tamil Nadu), and *Utrani* (Dharwar). Sometimes the pots are arranged one above the other vertically in descending order based on their size from the bottom to reduce the space requirement and these are called *Paanai* or *Addukkupaanai* in Tamil Nadu (Kiruba, SamManohar Das, & Papadopolous, 2006).

Dry land farmers generally stored seed in jute bags. The advantage of using bags is that infested bags can be removed and treated easily and such storage also avoids the problem of the “sweating” of grains because the surface is exposed to the atmosphere (Kartikeyan, Veeraraghavantham, Karpagam, Firdouse et al., 2009).

In humid areas seeds are stored in tightly woven bamboo containers of different capacities 5–10 kg. These are plastered with mud and cow dung on the inner side and for sealing. Their shape may be conical, cylindrical, or spherical according to the dictates of custom and convenience. They are known by different names in different regions as *Khaniki* in Koraput Orissa, *Rigal, tukuri* in Assam, *Urai* in Tamil Nadu, and *Chabri* in Himachal Pradesh (Sarangi, Singh, Singh et al., 2009).

About 100–250 kg of produce is stored in replaceable bins constructed regularly with straw, mud, bamboo, wood, or some combination of these. In areas of heavy rainfall (in the North-east and Uttarakhand) where grain cannot be dried adequately prior to storage and needs to be kept well ventilated during the storage period,

traditional granaries are usually constructed with timber, reeds, midribs of toddy palm, or bamboo. Bamboo structures are made on a raised timber or stone platform to protect the grain from rat damage and prevent moisture absorption from the ground. They are called by different names such as *mar*, *dully* (Northeast) and *Urai* (Dharwar). A small pothole is left at the top which is closed by *Cymbopogon* sp. Hackel (ginger grass). In Karnataka (*Kanaja/Galagi*) and Himachal (*Peru*), bamboo structures are plastered with a mud and cow dung mixture to prevent spillage and pilferage. Seeds are often stored in *Peru* as the germination rate of stored seed is high. The *Worli* tribe of Maharashtra state store paddy inside a cylindrically folded bamboo mat coated with dry grass and mud.

Straw or rope bins are the most effective indoor storage structure in Bengal, Bihar, Tamil Nadu, Orissa, and Jharkhand. They are called *Mora* (Jharkhand), *Dhoosi* (Koraput Orissa), and *Thallpai* (Tamil Nadu) and have a capacity of about 100 kg. The paddy is enclosed in loose straw and bound together by means of straw ropes. This allows for the penetration of air and the seeds remain viable for about 2 years and free from any insect infestation for 4–5 years (Jha, 1991; Kiruba et al., 2006; Singh & Singh, 2007).

Wooden bins are used mostly in hilly and cold areas especially of Assam, Maharashtra, Karnataka, Himachal Pradesh, Uttaranchal, and Kerala with a capacity of 40–100 kg. The wooden structure provides strength and provision for locking. It is topped with leaves of locally available plants like *A. indica*, *P. pinnata*, *Annona squamosa* L., and *Eucalyptus globules* (L.) Pierre. The wooden bin made by the *Khasi* tribe is called *drli*, and a double-layered bamboo basket, plastered on both sides with cow dung and mud, is placed inside it.

Various types of mud bins are made by using clay, soil with plant fibers, or husks of cereal grains having a storage capacity of up to 40–80 kg. The height ranges from 1 to 3 m. with narrow mouths or openings at the top which is closed with a tightly fitted lid. A circular vat like a baked bin with tapering ends, made with rice

bran and paddy straw is called *Kulumaij* in Tamil Nadu. It is a common practice to top up the *Kulukakai* with dried leaves of *Pongamia pinnata* and *Azadirachta indica* A. Jussieu (Kartikeyan et al., 2009).

Permanent, storage structures, inside the house for bulk storage, are usually associated with dry climatic conditions, under which it is possible to reduce the moisture content of the harvested grain to a satisfactory level simply by sun drying it. These structures are named according to their shape and the raw materials used.

A proper room constructed with a large door for pouring grains with bricks or clay with wheat straw and cow dung is called *Kothi*. In south India if the platform of the granary room is made of wooden boards and sides and has brick and cement walls, it is called *Macchu*, and if a strong concrete base stone is used, it is called *Kalangiyan*. If bricks are pasted with a mixture of diluted lime and sand lime mortar and the inner walls are lined with Palmyra leaf mats, it is called *Kaambara* (Kartikeyan et al., 2009).

Wooden structures of various dimensions are used by cultivators for storing paddy in hilly and cold areas of Assam, Maharashtra, Karnataka, Himachal Pradesh, Uttaranchal, and Kerala. These are generally made by wood of *Acacia* sp. and rectangular in shape (Kartikeyan et al., 2009).

Various types of bamboo structures are used inside the house in hilly and humid zones with a storage capacity of 600–1,000 kg. In Cachar district of Assam, the Dimasa community constructs various types of bamboo structures called *Mico*. *Micos* are constructed using seasoned wooden poles, bamboo, cow dung (Muski), neem (*Azadirachta indica*) leaf extracts, and soils of paddy land (locally known as Haa) (Das & Ray, 2013). Verma, Roy, Mary Swarnalata et al. (2005) reported that bamboo structures, though light and cost-effective, are moisture proof but susceptible to attack by wood borers. Wooden boxes give protection from moisture, rodents, and insects but require carpentry skill.

Outdoor storage structures are generally used to store huge quantities of rice. Stores are raised

on stone platforms using clay, red soils, cement, and bricks with the top portion covered with a conical shaped roof using bamboo sticks and palm or coconut thatch; they are known as *Kodambae*. The biggest grain storage structure built in a circular fashion by using calcareous soil containing clay particles is known as *Kudhir*. These storage structures are durable even up to 100 years (Sundaramari et al., 2011).

Bamboo outdoor storage structures are generally used in Andhra Pradesh, Meghalaya, and Assam. The structure is suitable under highly humid conditions. These are generally erected on bamboo poles or wooden platforms. In Andhra such structures are made with paddy straw alone (*Pari*); in Karnataka they are made of straw mixed with mud (*kacheri*), and in Assam these are prepared by bamboo and mud which are plastered and painted with clay and cow dung (*Gummi*). Grain bags are placed inside *Gummi* (Jeeva et al., 2006).

Nahu, a traditional system of storing rice in Arunachal Pradesh, is an example of community storing. Clusters of *nahu* are constructed at one corner of the village, away from houses, to protect them from fire. The ground below is used to store fuel wood (Singh & Bag, 2002). *Nahu* is used for 20 years and Toko palm leaves for roofing are changed after 5 years (Sarangi et al., 2009).

Underground Storage Structures.

According to Jeyarajan (2000), the first known method practiced for grain storage in large quantities was underground pits in areas where the water level was low. These are known by different local names in various regions and can be both inside and outside the house to save space for storage. They may be circular or rectangular and may be lined with cow dung, stones, sand, or cement. A layer of straw is placed all round which absorbs moisture from entering the soil and creates an oxygen-free atmosphere. In Karnataka it is called *Hagevu* and the pit is lined with straw ropes. The outer opening is sealed off with chaff, clay, and cow dung plaster; it had to be maintained well as the monsoon downpour tended to wash it away. Grains are generally

free from the seasonal variations in temperature and humidity. In case of pitted grain, because of the heat developed, curing is hastened and a sample in the pit for a couple of months is equivalent to 1-year-old grain. Grains can be stored without damage from insects and moulds for a longer period. However, it becomes cumbersome to take out the grains from these structures. *Khātā* (underground) were in vogue during Sultanate period. Ibn Baṭṭūṭa (1,340) recorded preservation of rice for long spells, stretching from 20 to 100 years in *Khātā* which were lined with dried, bull grass (*Bromus erectus* var. *pannonicus*). Although grains turned black after such long storage, they tasted good (Naqvi, 1984).

Storing of rice was considered serious undertaking and special rites accompanied this process. In Mizoram, after storing rice in a granary (Jhumhouse), a rite called *Sikisa* would be performed in which a white fowl or a dog would be sacrificed and the family would come to the village to eat, and while returning to the village, a bamboo whistle would be blown to call back the spirits from the *Jhum* to the village (Ray, 1993). In Manipur, *Meiteis* worship the paddy room by adoration of the granary and a rite is performed in the month *Wakching* by offering materials and *pooja* called *Kotlai Khurumba*. In Mizoram, after the storage of grain in the granary, a pig or a red hen would be sacrificed in the granary invoking the paddy to increase and last from the present winter to the next so that the family would have sufficient rice (Ray, 1993).

With the passage of time, traditional storage structures are diminishing and being replaced by metal bins. Rural people feel that traditional storage structures require regular maintenance and need local skilled persons whose number is decreasing for their construction. These storage systems obviated the need for employing residual insecticides and fumigants with the accompanying hazards they posed to the users and the environment. Integrating these indigenous knowledge systems into current research could develop appropriate new modern techniques for storing the grains in dry tracts (Kartikeyan et al., 2009).

Road Building in the Amazon

Stephen G. Perz

University of Florida, Gainesville, FL, USA

The Amazon basin has long been seen by national governments in South America as a region of low population density but rich in natural resources and is in need of economic integration to support national development. This has influenced the geopolitics of the Amazon and prompted governments and other organizations to promote road building in the region. New or improved roads are key for providing access to natural resources, and

highway networks thus link sites of resource extraction to urban markets and ports.

There have been arguably two distinct waves of integration initiatives in the Amazon. The first transpired in the 1960s and 1970s and was driven primarily by geopolitical concerns of national governments to secure their borders in remote corners of the basin in order to support integration of the Amazon with other regions within their countries (Goodland & Irwin, 1975). The second wave, since the 1990s, has been impelled by governments and multilateral banks seeking to complement national road networks with cross-border infrastructure in order to facilitate trade among neighboring countries. The second wave is encapsulated under IIRSA, the Initiative for the Integration of Regional Infrastructure in South America (CEPEI, 2002; Dourojeanni, Barandiarán, & Dourojeanni, 2010; Killeen, 2007).

Government-led infrastructure projects have in turn stimulated other road building in the Amazon. It is useful to distinguish between “official” (or “primary”) roads built by governments and “unofficial” (or “secondary”) roads constructed by other interest groups (Perz, Overdevest, Arima, Caldas, & Walker, 2007; Perz et al. 2008). These two types of roads differ in various respects, including the geometric forms of their networks in landscapes, as well as their relationships with natural resource exploitation and thus economic outcomes such as local development as well as environmental outcomes such as deforestation. Regardless of the type of road in question, road building in the Amazon (and elsewhere) has been a cause for debate due to the mix of significant positive and negative impacts.

Economics literature on infrastructure was stimulated by studies that showed large impacts on economic growth (e.g., Aschauer, 1989). Public sector investments in infrastructure appeared to generate large increases in private investments that expanded employment and per capita GDP. A macroeconomic literature has consequently emerged on infrastructure and its implications for economic growth. The findings have generally been positive and significant,

especially in developing countries, including Latin America (Bourguignon & Pleskovic, 2008; Straub, 2008). Positive effects of infrastructure on growth also apply to the rural sector. The macroeconomic literature is complemented by a microeconomic literature on roads and poverty in developing countries. There the emphasis is on making road investments to maximize livelihood benefits and rural poverty reduction (Howe & Richards, 1984; van de Walle, 2002). Empirical studies show significant poverty reduction near roads, whether via analysis of subnational administrative units (e.g., Demurger, 2001; Fan, Hazell, & Haque, 2000), communities (e.g., Gunasekera, Anderson, & Lakshmanan, 2008; Pender, Jagger, Nkonya, & Sserunkuuma, 2004), or households (e.g., Gibson & Rozelle, 2003; Jacoby, 2000).

But if the economic literature has offered positive evaluations of infrastructure, ecological research on roads has compiled a long list of negative consequences. There are multiple reviews of the ecological impacts of roads (e.g., Forman & Alexander, 1998; Trombulak & Frissell, 2000). This has fostered the specialty of “road ecology” (Coffin, 2007; Forman et al. 2003). The road ecology literature pays particular attention to spatial aspects of road impacts on biophysical environments. Reviews often take as their point of departure the observation that roads fragment habitats and modify stream networks. From there, ecologists have catalogued a host of consequences ranging from habitat isolation and degradation, to road avoidance by wildlife, to contagion effects such as exotic species invasions, among others.

A parallel literature on tropical forest fragmentation, notably in the Amazon, has also emerged and has a similar list of fragment edge effects on a variety of ecological outcomes (e.g., Laurance & Bierregaard, 1997; Laurance et al. 2002). Both the road ecology and habitat fragmentation literatures focus on the spatial configurations of habitat mosaics and the distance up to which specific ecological effects are felt, whether from roads or habitat edges. One implication is that the extent of spatial effects of a road varies considerably depending on the type of

outcome under study; another is that areas closer to roads and habitat edges tend to be more heavily impacted.

A more scattered literature exists on the social impacts of roads. One concern has been the distribution of benefits among distinct social groups. Social research has problematized differential benefits to higher status groups (Mahapa & Mashiri, 2001; Shriar, 2009) and districts closer to new infrastructure (Rudel & Richards, 1990), often as the result of a lack of broad participation in infrastructure planning (Devres, 1981; Robinson, 2001). Lack of participation also raises issues of exclusion of indigenous and other minority groups, often where newcomers make legalistic claims to natural resources in order to discredit traditional claims. Such political pressure disrupts traditional livelihoods and indigenous cultures, something well known in frontier areas such as the Amazon (e.g., Davis, 1977; Leonel, 1992). In addition, roads in the Amazon are notorious for stimulating conflicts and violence over newly accessible natural resources (e.g., Schmink & Wood, 1992).

While different types of roads all have economic, ecological, and social impacts, the mix of these impacts is distinct among official and unofficial roads in the Amazon. Official roads are generally highways built by governments with the intent of integrating cities, regions, and even countries. Famous examples in the Amazon include the Transamazon Highway across the central Brazilian Amazon, opened in the 1970s (Walker, Perz, Arima, and Simmons (2011), and the Interoceanic Highway, paved in the southwestern Amazon across the Brazilian-Peruvian border under the first phase of IIRSA after 2005 (Perz et al., 2012). In these and other cases, governments and banks prioritized long-range linear corridors that linked strategic locations in different regions, permitting national or cross-border integration. While official roads have received considerable attention in debates over their environmental impacts in the Amazon, they form sparse networks in the basin, leaving large blocks of forest intact since parallel corridors are often hundreds of kilometers apart.

By contrast, unofficial roads are built by private interest groups. Whereas official roads are built for strategic purposes involving economic integration, which may indirectly lead to economic, environmental, and social change along highway corridors, unofficial roads are built specifically to gain access to local natural resources. Hence, unofficial roads play a much more direct and instrumental role in local economic activity and environmental change. Indeed, opening or paving of official roads can stimulate unofficial road construction. There is thus a certain synergy between official road building and unofficial road construction. Further, to the extent that they permit profitable economic activity, unofficial roads can become autocatalytic, leading to unofficial road extensions to reach more remote natural resources as those available along established road segments become exhausted. Unofficial roads also differ from official roads because unofficial roads form much denser networks in landscapes because they are often spaced only a few kilometers apart, frequently follow winding paths, and have many intersections. Consequently, unofficial road networks fragment forest cover into smaller, more irregularly shaped, and often more isolated patches that are more ecologically vulnerable.

Debate over the economic, ecological, and social impacts of road building in the Amazon has led to calls for governmental promulgation of policies and investments in the enforcement of rules governing the management of natural resources (Nepstad et al., 2002). This in turn has prompted efforts to broaden public participation in infrastructure planning that can permit more inclusive distribution of the benefits of new or improved roads while mitigating or avoiding their problems (Mendoza, Perz, Schmink, & Nepstad, 2007). Official road corridors in the Amazon are characterized by rapid economic change and large inequalities among social groups in terms of preparedness and thus pose large challenges as well as opportunities for improved environmental planning (Mendoza, Perz, Souza da Silva, Brown, & Pinheiro, 2014).

Road Networks in Ancient Native America

Ruben G. Mendoza and Gretchen W. Jordan
Technology and Visualization, Institute for
Archaeological Science, California State
University, Monterey Bay, CA, USA

Pre-Columbian road networks in ancient America – specifically, the Southwestern United States, Mesoamerica, and Peru – provide a point of departure for exploring current issues in the study of non-Western technology. It should be noted that other major road networks have been documented for the Mississippian complex of eastern North America, Casas Grandes in Chihuahua, Mexico, and the Maya sacbe road networks of the Maya lowlands of Mesoamerica. These networks are currently the subject of ongoing investigations.

The three primary road networks of concern here are those of the North American Chaco Anasazi or Ancestral Pueblo of west-central New Mexico, Mesoamerican road networks centered on La Quemada and Xochicalco, Mexico, and the Inca system of Peruvian South America. These networks vary in scale, with the La Quemada complex representing a highly integrated, valley-wide network, dating to the period between AD 700 and 900. The Chaco network covers a circuit of over 300 linear miles of

ground-verified constructed road segments and features spanning the period from AD 920 to 1140. The Inca road network was expanded in a vigorous campaign to integrate all pre-existing road segments in the period between AD 1438 and 1532. This system incorporates over 2,000 linear miles of roads into the single most massive archaeological feature in the Americas (Hyslop, 1984).

The American Southwest

The formalized road network of Chaco Canyon, New Mexico, connects the canyon core with peripheral pueblo communities lying at relatively great distances from the core area. Over 500 miles of roads are indicated through the analysis of aerial photographs; however ground survey data are as yet incomplete, leaving unresolved the question of continuity in the network. The sociopolitical complexity of the Anasazi of the San Juan Basin is closely tied to the problem of road network continuity (Vivian, 1990). If the road network was contiguous throughout, this would support the contention that Chaco served an administrative function as the center of a regional system extending from Southwestern Colorado to South-eastern Utah, into Western Arizona and North-western New Mexico. Lack of continuity in the road network indicates a less integrated system, and a more autonomous character for the outlying communities.

Functional aspects of the Chaco road system are as yet unclear. Functional considerations center on the nature and control of goods transported as well as with the degree of interaction between core and peripheral communities. Proposed interpretations include (a) a defensive role for outlying pueblos, (b) protection of trade routes, (c) ceremonial functions, (d) political administration, and (e) the transport of subsistence-related goods. It has also been suggested that outlying pueblos served as rural sustaining communities directly affiliated with representative groups of the canyon core (Kincaid, 1983).

Chacoan road construction exhibits several characteristic features. Most notable is the

absolute linearity of the roads, despite potential topographic obstacles. The great North Road deviates $<1^\circ$ from its northerly course in over 46 km. Masonry road elements such as flanking walls, or curbs, ramps, and raised roadbeds also characterize the system. Several architectural features are associated with road segments. These range from simple cairns and shrines to residential room-blocks and Great House communities with Great Kiva ceremonial structures. Stylistically uniform, these features and structures employ Bonito-style construction of core-veneer masonry and massive walls.

There are no historical data available describing the Chacoan road system. To date, all interpretations have been based on archaeological research and remote sensing techniques. Gordon Vivian pioneered this research in 1948. From 1971 to 1977, the Remote Sensing Project of the Chaco Center – in conjunction with the National Park Service and the University of New Mexico – undertook investigations of the Chacoan road network. Their efforts focused on the use of ground verification studies for the extensive mapping of road alignments appearing in aerial photographs. From 1980 to 1983 the New Mexico Bureau of Land Management undertook a comprehensive effort to document the road network by means of ground verification (Kincaid, 1983).

Mesoamerica

Studies pertaining to Mesoamerican road networks are relatively recent, and most such studies have emphasized ground verification and mapping. The sites of Casas Grandes, La Quemada, Xochicalco, Teotihuacan, and the Maya lowlands have been the subject of most surveys to date, while the Tarascan and Sonoran regions have been the subject of the most recent surveys. The road networks of these regions provide a glimpse into both the Late Classic, and the Protohistoric developments of the fourteenth through sixteenth centuries AD (Mendoza, 2001).

The area of La Quemada, Zacatecas, lies within a semiarid region of Mesoamerica's Northern

Frontier. This area is dominated by a series of hill-fort centers, each of which is characterized by the presence of civic-ceremonial precincts, agricultural terraces, and secondary centers with related defensive features. An extensive intra-regional network of roads connected the primary centers of La Quemada and Los Pilarillos with secondary centers, and in turn, isolated mound groups, isolated platforms, defensive positions or fortifications, and agricultural terraces. This system, by contrast with that of Chaco Canyon, served to integrate communities within a tightly constricted area. Road segments linking the La Quemada road network with regions beyond the valley have yet to be fully mapped or verified.

The specific road-related features identified with La Quemada include (a) formal causeways or other elevated road segments; (b) road segments terminating at elevated platforms; (c) causeways of between 5 and 7 m to 12 and 14 m in width with road-bed elevations of between 30 and 40 cm; (d) causeways that extend to wide, low platforms and stairways with precipitous descents down steep escarpments; (e) parallel road and canal or other irrigation segments; and finally (f) where the larger causeways are concerned, such roads are identified with defensive positions. At La Quemada, the aforementioned features are taken to represent a sociopolitical pattern geared to militarism or related defense activity (Trombold, 1991b).

Where the road networks of the Mesoamerican Epiclassic era (ca. AD 650–900) are concerned, the central Mexican city-state of Xochicalco, Morelos, provides a salient example. The site of Xochicalco, like its La Quemada contemporary, is situated in a strategically located acropolis-centered hill-fort locality. Most of the road segments identified with Xochicalco emanate from the hill-fort to other centers within the valley below, and as such, Xochicalco provides a characteristic example of roads as symbols of power, prestige, and levels of regional integration. In other words, this position holds that Mesoamerican road networks function primarily as mechanisms for social integration or as symbols of the power and prestige of social or religious elites (Hirth, 1991). The scale and

magnitude of construction activity invested in the road systems of Mesoamerica have led some scholars to speculate that such roads were less functional and more ceremonial in character. Monumental construction and related public works are taken as indicators of political power, and thereby elite command of critical resources (such as slaves and construction personnel) in the valley during the pre-Columbian era (Trombold, 1991a).

Mesoamerican economic systems, by virtue of the nonexistence of draft animals, and thereby, wheeled vehicles, were limited to human burden bearers. Despite this limitation, such systems were every bit as formal as those of other Old and New World polities. Primitivist interpretations of New World economies have unnecessarily minimized the perceived scale of economic formations in Mesoamerica and the New World despite available ethnohistorical data. The extent and magnitude of investment in road construction, and scale of integration made evident by the contiguity in the system, is again a key indicator of the types of sociopolitical formations that once prevailed in Mesoamerica. The Aztec era provides only a hint at what prior civilizations engaged in the way of road network investment in construction and maintenance, and by any account, the investment was substantial and culturally significant. Robert Santley's recent projection of road networks for the Basin of Mexico presents us with a system that was highly integrated and equally complex (Santley, 1991).

The utility of a formalized – organized, linear, weatherproof – road network over which to maintain the movement of goods and services was critical to trade and exchange in Mesoamerica. Like the ancient informal paths that preceded them, formalized roads served to guide and expedite the movement of goods and services on both an intra- and inter-regional scale.

A typology of Aztec era roads was recorded by Fray Bernardino de Sahagun, the sixteenth century Franciscan cleric who documented such aspects of postconquest central Mexican culture (Sahagun, 1963). Of the seven types of roads identified by Bernardino de Sahagun the

ochpantli and oquetzalli road types have been isolated as representative of the Xochicalco road types. The first term pertains to the “main road” and the second to the “royal road” networks of the Aztec era. The well groomed roads of Xochicalco are interpreted as the royal road type. This interpretation is based on the monumental nature of the associated architecture (primarily defensive in character), the cut-stone pavements, and the relatively large width of the roadbed itself. In addition, archaeologist Kenneth Hirth distinguishes between “road” and “thoroughfare.” Roads are “transportation arteries at the regional level which connect two or more spatially separated sites”; thoroughfares are “streets and other communication corridors which organize space and/or direct traffic flow within the community” (Hirth, 1991). The fragmentary nature of the data precludes a region-wide economic and social interpretation of the Xochicalco network.

The Xochicalco road network exhibits a number of distinct architectural characteristics, including:

1. Stone-surfaced intra-site rough-cut mosaic pavements or roadbeds of 3–5 m widths
2. Intra-site masonry ramps
3. Parallel platforms flanking key road segments or thoroughfares leading into the site core area
4. Roads which bisect massive rampart walls with narrow gateways in order to access intra-site thoroughfares
5. Intra-site pavements or roadbeds edged with cut-stone masonry blocks
6. Stucco used along flanking masonry edging in the intra-site sectors
7. Intra-site pavements made flush with surfaces traversed and modified with ramps – both smooth and stepped
8. Lateral masonry walls flanking intra-site pavements
9. Access causeways along circuits of defensive ditches or moats
10. Evidence for the use of a probable wooden bridge spanning a defensive moat adjacent to Cerro de la Bodega

Transport architecture extending beyond the site perimeter consists of less formal construction techniques in addition to significantly less evidence of overall integration with the site core of Xochicalco.

Recent studies provide indications of a massive road network that connected the Classic period center of Teotihuacan with an ancient trade corridor linking that site with the Puebla Basin, and by extension, the Mexican Gulf lowlands. Unlike the more defensive character of the La Quemada and Xochicalco road networks, the Teotihuacan corridor linking Teotihuacan with a whole host of ancient mercantile centers in the Mesoamerican highlands and Gulf coastal plain served a key transport function for the movement of goods and services provisioned and sought by Teotihuacan.

The road-associated settlement hierarchy of the Teotihuacan Corridor, as well as the recent identification of specific features of transport network architecture along the Teotihuacan Corridor, is currently under study. Additional features of Mesoamerican transport network architecture include (a) causeways – such as the Street of the Dead – measuring some 40 m in width; (b) the presence of Momoztli structures, or elevated platforms or shrines (often laden with trade offerings) situated at the crux of important crossroads along the corridor; (c) an approximate inter-site road width of 24 m, and 60 cm depth, for sites located on the Teotihuacan Corridor; (d) spur roads that connect road-associated settlements with the principal arteries of the Teotihuacan Corridor and with other key nodal points or market centers; (e) related architectural styles and construction along the course of the transport network; (f) roughly equidistant spacing of road-associated settlements at 8–9 km intervals for specific Teotihuacan related centers; and (g) stepped ramps, road shrines, crossroads, and attendant roadbed linearity. The overall network is dendritic in structure, in that the main road connects with primary centers, which are in turn connected to a constellation of secondary centers sharing affinities with key terminals along the Teotihuacan Corridor.

Peru

The most intensively studied ancient road system of South America is that of the Inca Empire, extending over a vast area from Ecuador to Chile, from the coastal deserts to the Andean highlands, into the Bolivian forests. This network included some 20,000 miles of roadways and encompassed 40,000 miles at the point of European contact. This road system constitutes “South America’s largest contiguous archaeological remain,” and provides valuable insights into the organization and technology that are hallmarks of the Inca state (Hyslop, 1984).

In contemplating the vastness of this road network, one is struck by the enormity of the Inca achievement. First, there is the effectiveness of the political infrastructure that organized and mobilized a labor force specialized in the building and maintenance of roadways. Second, the Inca were exceptionally efficient in their use of resources, both natural and human. Pre-existing roadways were frequently incorporated into the Inca network. Inca engineers did not seek to modify natural topography to any great extent unless required to do so in order to achieve safe passage. Where road modifications were concerned, locally available materials were utilized and work was performed by locally organized labor pools under the supervision of a road administrator. Third, the Inca brought to bear a vast body of technical knowledge and expertise, accumulated over the course of centuries among the diverse ethnic groups of the empire. Finally, the efficiency of the road network insured that Inca rulers could maintain communication with – and thereby, the integration of – every corner of the empire.

Four primary state roads divided the empire into cosmologically defined quadrants (Urton, 1981). The sacred geography associated with road networks reflected the Inca preoccupation with cosmology defined *vis-à-vis* extant social divisions. Cuzco, the political and administrative center of the Inca state, was linked via these sacred paths to the most ancient shrines and temples. Roadways not only defined the

partitioning of sacred space, they also served as linkages in a massive transport and communication network.

Road characteristics varied considerably in terms of construction methods and the extent of labor investment. Construction methods varied with the highly fractured and variable topography of the region, and as such, a single road might include both road segments with very complex architectural features and evidence for intensive labor investment, and simple unpaved or earthen pathways. Ultimately, road construction varied with localized conditions, topographic obstacles, available materials and labor, and the importance of the specific road segment to ceremonial and ritual activities.

Coastal routes varied from simple “pole-roads” to broad thoroughfares with stone or adobe sidewalls. Pole-roads were paths marked by linear arrangements of wooden posts placed at intervals. High-altitude roads on nonagricultural lands were, by contrast, engineered for durability in order to withstand harsh climatic conditions. Such roads incorporated elaborate stone curbs, retaining walls, and paving. These later constructions are among the best-preserved roads in evidence for the Andes. Roads traversing agricultural fields are characterized by very high sidewalls – of 1 or 2 m in height – designed to protect crops from travelers or livestock such as llamas and alpacas. Such walls were likewise built of stone or adobe. Agricultural roads were relatively narrow so as to minimize their impact on the availability and productivity of arable lands.

Where roads crossed wet plains or slopes, stone paving was used to preserve the roadbed. If flooding was unavoidable, the road was constructed on an elevated surface or causeway. Inca causeways were of rubble-core construction, with or without stone retaining walls. In those instances where existing slopes were $<10^\circ$ off horizontal, the Inca used a combination of stone or rock-cut ramps, stairways, or switchbacks in order to buffer ascent and descent. Depending on the steepness of the existing slope, structures ranged from a single retaining wall to a series of walls and benches built on the downhill side of

the slope, and intended to serve as secondary retaining features.

Bridges are among the most spectacular structures engineered by the Inca. While sixteenth century European construction employed the principle of the arch in bridge construction, the Inca were able to span greater distances through a variety of engineering principles and techniques. Early Spanish explorers marveled at the sight of Inca suspension bridges which were unknown in Europe. Though made of woven and braided fiber coils, these suspended structures supported considerable pedestrian traffic, in addition to European horses and carts of the conquest period. Other types of spans built by the Inca included floating bridges supported by pontoons of reed bundles, wooden bridges manufactured from logs placed over stone abutments (with or without cantilevers), and a variety of stone bridges. Culverts were stone-lined troughs left open, or capped, if necessary for safe passage. Somewhat wider rivers were spanned by stone columns placed adjacent to one another, thereby forming “multicell” culverts which supported the overlying roadbed. Some stone bridges employed cantilevered abutments supporting very large stone pavers. Finally, natural rock formations were utilized as bridged areas where available.

An integral component of Inca era road networks was the *tambo* system. Tambos were multiuse structures or facilities maintained by the Inca state but administered locally. Hyslop estimates that between 1,000 and 2,000 of these facilities were in use throughout the Inca empire. Tambos exhibit considerable variation in size, ranging from sites with a few isolated structures to large administrative centers representing a multitude of activity areas. Storage and lodging constitute the primary uses for which tambos were employed. Storage structures included silos, corrals, and adjoining rooms. Lodging in tambo facilities was temporary, and intended either for travelers or as permanent residence for local administrators. Tambos were also employed in the processing of raw materials, military and ceremonial activities, local administration, and craft production. Tambos were equidistantly spaced on any given route at intervals

representing a day's travel time. According to recent Inca road surveys, *tambos* were spaced at intervals that average between 15 and 25 km. The combined *tambo* system and vast complex of roadways formed a critical component of the state's infrastructure. This highly efficient transport and communication network supported the state's practical needs for efficient military mobilization, colonization, economic maintenance, and administration. In addition, the complex network of roads supported the ideological needs of the Inca hierarchy, providing a highly visible set of linkages between the people and the state.

Rock Art and Folk Islamic Practices in Central Asia

Kenneth Lymer

Wessex Archaeology, Salisbury, UK

Many of the Muslim peoples living within the Central Asian republics of Kazakhstan, Kyrgyzstan, and Turkmenistan carry out indigenous expressions of religion generally referred to as folk Islam. Some practices derive from pre-Islamic times, while others represent new forms of spirituality developed in response to their historical circumstances. Nevertheless, the most prominent feature of Central Asian folk Islam involves visiting a *mazar*, a holy place. Throughout the Muslim world, the common alternative to the *hajj*, the pilgrimage to Mecca, involves the practice of *ziyarat* (Arabic), continual visitations to the tombs of saints. Additionally, among the peoples of Central Asia, journeys to major holy shrines or mausolea located in or nearby urban areas can be an acceptable equivalent to the *hajj* as well as that of visiting special mazars in the countryside.

The Arabic word for saint is *wali*, god's representative, and it has been adapted into Kazakh as *auliye*, Kyrgyz *oliya*, and Turkmen *öwliýä*. Moreover, these latter words can also refer to the saint's burial place from which *baraka*, spiritual power, emanates from the tomb. Islamic saints are chosen by localized historical factors, and a Central Asian saint may have been once the heir of a Sufi master or an individual who had performed miracles during his or her lifetime.

Central Asian mazars are not only connected to saints but also have associations with prophets, heroes, ancestors, and spirit guardians. The mazar does not have to be a tomb and could be the cemetery where clan ancestors lie buried or sacred trees and springs, which are protected by spirit guardians. Most mazars possess healing powers and are sought by pilgrims in search of cures for physical or spiritual illnesses and also by women seeking to become pregnant. Moreover, these holy personages may reveal themselves to the pilgrim in

a dream at a mazar or appear in dreams instructing an individual to go on a shrine pilgrimage. This, in turn, reflects the medieval Sufi heritage of Central Asia as there is a cultural background of observing *ayan* (“personal revelation,” Arabic), the illuminationist dimension of Sufi spirituality, which manifests in dreams and impels religious activities.

Rock Art Mazars

Ethnographers and explorers since the nineteenth century have documented the various ways in which the peoples of Central Asia recognize special places in nature as sacred sites, such as trees, springs, stones, and caves, or secluded spots in valleys and mountains. Such places are usually identified by the accumulation of rags tied to the branches of local trees and shrubs or wrapped around poles and stones. Sometimes a formal structure may be constructed upon the site to enclose the natural feature.

Moreover, there are numerous rock art sites found in the rocky outcrops of Central Asia and their age can range from prehistoric to ethnohistoric times. Depictions feature a variety of human and animal figures as well as abstract and geometrical shapes, and many scenes were, arguably, created with religious or ritual intent. The majority of these panels are executed as petroglyphs, images carved or pecked into natural stone, while the occurrence of rock paintings is quite rare. Petroglyphs can be found within the vicinity of a shrine, and there are several cases of the rock art site itself being treated as a mazar by local peoples. Additionally, there are other markings in the natural rock found at shrines, which are not artificially made, that pilgrims believe to be the footprints or bodily impressions of saints or heroes.

Perhaps, the highest mazar in Central Asia is the major rock art complex of Saimaluu Tash (“decorated stones,” Kyrgyz) that spreads across two valleys high in the Fergana mountain range, western Kyrgyzstan, at about 3,200 m above sea level. The Kyrgyz locals believe the prehistoric carvings were not made by human hands and

consider the area to be *iyik zher* (“holy” Kyrgyz). It is a place of pilgrimage for groups who seek healing and women come here to cure infertility. Pilgrims bring livestock to be killed and eaten in a ritual meal accompanied by prayers and readings from the Qur’ān. During times of epizootic spreads of animal disease in the recent past, entire cattle herds have even been brought up to Saimaluu Tash to receive protection from harm.

Meanwhile, the shrine complex of Sulaiman-Too in the city of Osh, southern Kyrgyzstan, covers the entire mountain, which is named after the Muslim prophet Sulaiman (King Solomon). Sulaiman’s shrine is a small cave that is believed to be his grave and pilgrims pray here asking for reprieve from illnesses and other forms of help. Additionally, a mosque for the prophet was built on the eastern side of the mountain in the sixteenth century. According to legend, this is the place where Sulaiman admired the mountain and is affirmed by the presence of handprints which he is believed to have left in the rock.

The petroglyphs of Sulaiman-Too are situated in spots around the mountain on exposed surfaces and found inside caves and date from the Bronze Age to Medieval and later times. Kyrgyz pilgrims visit the rock art localities for blessings and healing from ailments, such as *Kol Tash*, “the hand stone” (Fig. 1). There is also a rock art panel that is believed to treat only headaches, while another bestows longevity upon children. Additionally, the Chiltan-Khana cave – named after chiltens, helpful spirits – located on the southwestern slope has many abstract images and local tradition considers the cave passage to be a pathway to Mecca.

Moving to southeastern Kazakhstan, there is the major rock art complex of Tamgaly valley, which is referred to by the local Kazakhs as *Tangbaly Aulie*, “sainted place of clan-markings.” The rock art is dated from the Bronze and Iron Ages to Medieval times. Large bushes growing near the river are covered with numerous rags tied by pilgrims seeking blessings, and visitors have even tied rags onto small jutting rocks near various petroglyph panels around the valley. Rags are also tied on the bushes growing beside the

famous scene of six Bronze Age “solar gods.” Locals believe the ground in front of this scene was once the grave of an unknown saint; however, archaeological excavations of the site did not find any evidence for such a burial.

Another sainted rock art site is Terekty-Aulie, an area of granite hills covered with Bronze Age petroglyphs that is situated north of the city of Jezqazghan in Central Kazakhstan. An important nineteenth-century cemetery was also founded at the base of the highest hill. Pilgrims had erected

a stone shrine (Fig. 2), which more recently has been replaced by wooden post, atop this hill in the natural crevice between two large petroglyph panels depicting numerous horses. Rags once covered the stone shrine and are now tied to the post as well as to any stray bush growing from the cracks in the hillside (Fig. 3). After visiting the shrine, Kazakh pilgrims return below to have a ritual meal involving the sacrifice of a live goat, which is accompanied with prayers and Qur’ān readings. They then visit the cemetery to commemorate the ancestors and tie rags to its fence.

Terekty-Aulie is a place of healing and its baraka derives from a visit by the prophet Khazrat Alī – ‘Alī, the son-in-law of Muhammad. There are also rock art images of his footprints as well as petroglyph hoofprints belonging to his faithful horse, Duldul. Furthermore, at Duldul-Ata in southern Kyrgyzstan, there is a small rock art site situated near a holy spring featuring the ancient petroglyphs of two horses. The name of this curative mazar derives from ‘Alī’s steed, and according to local legend, an invisible horse spirit once dwelled here that could only be heard by certain individuals. There is also a mysterious tomb of an unknown individual at this site, which is now enclosed by a mausoleum structure.

The important Hazret Ali shrine located southwest of Ashgabat, Turkmenistan, is another

Rock Art and Folk Islamic Practices in Central Asia, Fig. 1 A natural hole with small petroglyph images around its edges that is known in Kyrgyz as Kol Tash, “the hand stone” (Sulaiman-Too, Kyrgyzstan)

Rock Art and Folk Islamic Practices in Central Asia, Fig. 2 The shrine stone erected above petroglyphs at Terekty-Aulie, Kazakhstan, as seen in 2001 before its replacement by a rag post

Rock Art and Folk Islamic Practices in Central Asia,

Fig. 3 A prayer rag tied to a small bush found along a hillside at Terekty-Aulie, Kazakhstan

mazar with impressions in the rock that are believed by the Turkmens to be derived from ‘Alī’s hands and the hooves of Duldul. Moreover, there is an impression of a human body in a fetal-like position in a large boulder where pilgrims believe he lay down to rest.

Female saints can also leave markings for the faithful. At the shrine of Paraw Bibi in western Turkmenistan, there are impressions of knees and hands in the natural rock left by this holy Turkmen hero (*batır*). Pilgrims come from around western Turkmenistan to the shrine for healing, and there are also miracle-working stones that can be used to predict the future. Additionally, there is a small cave through which she is said to have entered into the mountain, and here young women come recite prayers for her blessings and to cure infertility.

In conclusion, it is important to consider that folk Islam is part and parcel of people’s engagements with the tangible and intangible aspects of the landscape. Concentrations of rock art images, like trees, stones, springs, and caves, can in effect become the medium through which people affect change in the world by seeking out their sacred properties. Furthermore, the rock art mazars are also situated at the crossroads of time where present-day practices acknowledge and

dynamically interact in exceptional ways with the artistic and religious endeavors of past societies.

Rocket Machinery of the Mamluks

Vasileios Christides

The Institute for Graeco-Oriental and African Studies (IGOAS), Kryoneri, Attikis, Greece

Rockets for launching Greek fire by means of shooting flying fire arrows (*sihām khiṭā'i*) propelled by a primitive form of gunpowder appear in a number of Arabic military treatises, written mainly in the Mamluk period (1250–1517). The Mamluks paid special attention to the composition of military treatises known as *furūsīyah*, which were precious sources extensively describing horsemanship, military training, and weaponry (Al-Sarraf, 2000). S. al-Sarraf correctly remarks that a number of these treatises, mainly anonymous, had already been written before the Mamluk period and were reproduced with a few additions (Al-Sarraf, 2004, p. 143). The *furūsīyah* treatises are invaluable for the information they offer on pyrotechnic technology although they frequently recycle older material mixed with contemporaneous.

One of the most significant *furūsīyah* treatises by Najm al-Dīn Ḥasan al-Rammāh is called *Al-furūsīyah wa'l manāṣīb al-ḥarbīyah* (Horsemanship and ingenious war stratagems), written in the late thirteenth century (Al-Rammāh, 1998). It contains an admirable number of passages concerning weapons, mixing of various chemical materials, and war machines used not only on land but also in naval wars. He considers saltpeter the fundamental substance of pyrotechnics and, as Zaky points out, his description of the purification of saltpeter by crystallization preceded that of Roger Bacon (1214–1292) (Zaky, 1967, p. 49).

More important for the study of pyrotechnic technology are the *furūsīyah* treatises, *Kitāb al-makhzūn fī djāmī' al-funūn*, written by Ibn Akhī Hizām (dated to H875/1470, ms. C-686, Institute of Oriental Studies, St. Petersburg), and two by the fourteenth-century author Ibn al-Manqalī, i.e., *Al-adilla al-rasmīyah fī'l-ta'ābī' al-ḥarbīyah* (Ibn al-Manqalī, ed. Khaṭṭāb, 1988)

and *Al-aḥkam al-Mulūkīyah wa'l dawābiṭ al-nāmūsīyah*.

Ibn al-Manqalī provides us with unique information about the Greek (liquid) fire about which a great number of misconceptions have been created (Christides, 2013), although his remarks in the two abovementioned treatises are occasionally somewhat confusing because he was writing in the fourteenth century about Byzantine naval preparedness of the tenth century, based on the works of Leo VI's *Naumachica*. Thus, one of his significant remarks is his report that in every Arab warship, medical personnel was needed (Ibn al-Manqalī, 1988, p. 245). Obviously, such personnel must have also existed in every Byzantine warship, although it is not reported in any Byzantine naval treatise; it is only mentioned by the Byzantine author Constantine Porphyrogenitus (Karapli, 2013). More important is Ibn al-Manqalī's short reference to some Arab small-size warships especially equipped to launch fire arrows in order to burn enemy ships (Ibn al-Manqalī, 1974, p. 39). Ibn al-Manqalī reports that special personnel embarked on these ships under the guidance of the leader of the fire throwers (*muqaddam al-zarāqah*), well trained to operate the incendiary weapons. Unfortunately, few details are known about these operators of the incendiary weapons. They continued the function of the fire throwers, known as *naffātūn* or *zaraqūn*, who, as it has been shown by D. Ayalon, had been activated from early Islamic times and were used either in the sieges of towns or in the open battlefields (Ayalon, 1956, pp. 16, 36).

Ayalon's view that the units of the army trained for fighting in the open battlefields were abandoned sometime in the Abbasid period, due to the uncontrollable use of the produced fire, cannot be sustained. In contrast, at the time of Harūn al-Rashid (786–809), a whole regiment was composed of *naffātūn* who enjoyed great prestige thanks to their incendiary weapons (Zouache, 2008, p. 416; Elisséef, 1967, pp. 734–735).

Concerning the weaponry used by the *naffātūn*, it should be taken into consideration that it varied substantially through the long

period of their development from the early Islamic times to the end of the Mamluk era. In the early Islamic period, the *naḥḥāṭūn*'s task was to hurl fire bombs by hand or throw them by machines against the enemy's camp. The early fire bombs were stuffed with combustibles based mainly on a petroleum incendiary substance called *naḥḥ* (Christides, 2013, p. 147). Gradually, the incendiary mixture was replaced by crude gunpowder based on saltpeter, bearing the same name *naḥḥ*, and finally purified saltpeter, i.e., gunpowder called again *naḥḥ* and later *bārūd*, which was composed of saltpeter, sulfur, and charcoal (Christides, 1993, p. 886).

The chronological order of these transformations, discussed extensively by J. T. Reinaud and I. Favé (1845), D. Ayalon (1963), J. R. Partington (1999), S. G. Haw (2013a, b) and others, is beyond the aim of this article which is focused on the double development of the Arab naval weaponry of pyrotechnics under the Byzantine and Chinese influence culminating in the rocket machinery used by the Arabs for launching large fire arrows carrying cartridges of primitive gunpowder. Such machinery was used by the Arabs in both land and sea warfare and obviously can be identified with the weapon described briefly in the abovementioned passage of Ibn al-Manqalī, which, as it will be seen, was constructed by the Arabs under the influence of the Chinese naval technology, completing their knowledge based on the Byzantine naval technology. We can trace the incorporation of the Byzantine naval technology into the Arabic mainly after the eighth century following the second siege of Constantinople in ca. 717–718, during which the Byzantines made extensive use of the so-called secret weapon of the Greek fire (Strohmaier, 1989; Kollias, 1989, p. 31). The Arabs had also used a primitive form of Greek fire in this siege, as it is reported in the Arabic and Greek sources, but it is only sometime later that they became fully aware of the final form of the Greek fire during the Arab-Byzantine struggle at sea at the turn of the ninth century. At least in the year 825 AD, there is a concrete reference that whole Byzantine warships along with their crews were captured by the Arabs who, thus, acquired

complete knowledge of the so-called secret naval weapon of the Greek fire (Ibn al-Athīr, 1979, p. 339).

The acquaintance of the Arabs with the Byzantine naval technology enabled them by the tenth century to construct warships similar to the Byzantines with a main flame thrower mounted on the bow, stationed in a forecastle, and protected by a small guard of marines. Such large flame throwers could only be installed in a large average Byzantine and/or Arab warship whose length was approximately 30–40 m.

From the scanty information of the Arabic historical sources, it is evident that by the ninth century the small Arab warship, called *bārīj*, carried a crew of 39 including three naphtha throwers (Nakhili, 1979, pp. 10–11), who did not operate any machinery similar to that installed in the big warships, but instead they carried portable flame throwers, similar to those used by the *naḥḥāṭūn* of the land forces.

The construction of such portable fire throwers should be traced to the Chinese pyrotechnic technology. The Arabs had increased their trade relations with China in the Abbasid period and intensified them after the conquest of Egypt by the Fatimids in 969. Archaeological finds in Fustat (now a suburb of Cairo) of Chinese bowls and vases with fine incised designs reflect the strong trade relations between Fatimid Egypt and China (Gyllensvärd, 1975). Chinese influence on Arab naval technology and pyrotechnics continued especially during the time of the Mamluks. In a preliminary study, V. Christides (1992) expressed the view that the Arab rockets, composed of lances carrying Greek fire propelled by primitive gunpowder, as depicted in Arabic manuscripts, could have been constructed by the Arabs inspired by Chinese military technology.

Now a thorough study by Stephen G. Haw, a specialist in Chinese pyrotechnic technology, has enhanced this speculative theory. Based on literary and archaeological evidence, Haw has shown that fire arrows, from which rockets were developed, containing incendiary substances and/or gunpowder (or at least saltpeter, the vital ingredient of gunpowder), had existed in China since 1000 AD and explosive bombs as early as

Rocket Machinery of the Mamluks, Fig. 1 Chinese rocket arrow (Needham, 1964, Fig. 17, p. 248)

1150 AD, all widely used by the early thirteenth century (Haw, 2013a, pp. 442, 463; 2013b). Needham had already paved the way for Haw. He had reported that the Chinese literary sources describe fire lances (*huo ch'iang*), composed of a tube filled with rocket composition, held upon the end of a spear. He further added that such lances preceded the metal cannon which appeared in China ca. 1280–1320 and that the Chinese rocket arrows were originally made of bamboo tubes (Fig. 1) (Needham, 1964, p. 248). Needham's depiction of the Chinese rocket arrows strongly resembles the Arabic javelin rocket illustrated in an Arabic manuscript of the fourteenth century (Fig. 2) (Nicolle, 1999, Fig. 364a, p. 411).

It is undoubtedly that from this Chinese military technology, the Arabs drew their advanced pyrotechnic technology and their *naffāṭūn*, embarked on their small warships (*bārij*, pl. *bawārij*), mentioned above in Ibn al-Manqalī's passage, and carried portable flame throwers of irrelevant technology to those used in

Rocket Machinery of the Mamluks, Fig. 2 Javelin rocket carrying *naft*. Mamluk *furūsīyah* manuscript (fourteenth to fifteenth centuries) (Simplified sketch by D. Nicolle (1999), Fig. 364a, p. 411)

the big warships (*shīnī* corresponding to the Byzantine dromon), which were constructed according to Byzantine military technology.

Concerning the *naffāṭūn*'s naval weapons about which there is no particular information in the Arabic sources, we can assume that they were not different from a number of war machines described in the *furūsīyah* manuscripts. A. Y. Hassan describes several of them in a study (2006) with explanatory comments concerning their function and the composition of their ammunition. Unfortunately, they are dated after the twelfth century AD, and the transitional period, i.e., the end of the use of incendiaries followed by that of the explosives (ca. the eleventh to twelfth century), is sorely missing. The most interesting of them is the treatise *Al-anīq fī al-manājiq* written by Unbughā al-Zaradhash for the *atabāk* (chief commander of the Mamluk army) Manglī Bughā al-Shamsī, who was in office between 769/1367 and 774/1372 (Al-Sarraf, 2004, p. 184). An illustration in this treatise depicts a portable fire thrower which is a self-launching rocket, also reproduced in the anonymous treatise *Khizānah al-silāh* (Al-Sarraf, 2004, p. 180), published by Nabīl 'Abd al-'Azīz (1978, p. 70) (Fig. 3).

An Arabic inscription describes in detail the composition of the combustibles launched by the

Rocket Machinery of the Mamluks, Fig. 3

Arab propel rocket. Arabic drawing in *Khizānah al-silāh*. Ed. N. ‘Abd al-‘Azīz (1978). Cairo, p. 70. Reproduction from *anīq fī al-manājiq* of Unbughā al-Zaradhash (Courtesy photo by IGOAS. V. Christides et al. (eds.) (2004). *Treasures of Arab-Byzantine navigation* (7th–13th c.). Athens: IGOAS, p. 44)

Rocket Machinery of the Mamluks, Fig. 4

Model of an Arab machine for launching fire arrows stuffed with gunpowder. Construction by N. Orphanoudakis and N. Hadjitheodorou (Courtesy photo by IGOAS. V. Christides et al. (eds.) (2004). *Treasures of Arab-Byzantine navigation* (7th–13th c.). Athens: IGOAS, p. 23)

fire throwers: “You take ten dirhams [one dirham = 3 g] of bārūd [=this word means both saltpeter and gunpowder] one and a half dirham of charcoal, one and a half and one eighth of a dirham of sulphur and you grind [the mixture] until it becomes thin, and you activate a propelling arrow.” Although this machinery is called “cannon” by some modern authors, it is actually a self-launching rocket (Christides et al., 2004; Christides, 2008). The explicit meaning of cannon is “a large gun fixed to the ground or to a gun carriage which fires a solid ball of metal” (Hornby, Cowie, & Gimson, 1974, p. 123; for a distinction between rockets and cannon firing [solid] projectiles, see Nicolle, 1999, p. 296).

No solid metals are fired in the abovementioned machinery in Unbughā al-Zaradhash’s manuscript. Instead a primitive rocket is depicted, which is self-ignited, shooting big firing arrows, propelled by a primitive form of incendiary gunpowder, the essential precursor of explosive gunpowder. As stated above, Christides’ theory of tracing the origin of those rockets to Chinese technology has been enhanced with the new studies by Stephen G. Haw (2013a, p. 442) who, based on Chinese literary sources, has shown that the Chinese had invented such rockets developed from fire arrows, called *huojian*, already in the eleventh century, which probably originally carried an incendiary substance, replaced later by incendiary gunpowder.

Based on the accumulated information above, the Institute of Graeco-Oriental and African Studies (IGOAS), under the guidance of V. Christides, has twice reconstructed a model of the Arab propel rocket, first by N. Orphanoudakis and N. Hadjitheodorou (Fig. 4) and second by I. Kakaras and G. Bothos (Fig. 5). From these reconstructed models by IGOAS, it is clear that the rocket included cartridges filled with incendiary propelling material. It is not known whether this material was a self-ignited substance for launching fire arrows (*sihām khitā'iyya*) or whether it was needed to ignite it. The black powder ignites when heated to

A Chinese soldier launches fire arrows stuffed with combustibles (From R. D. Franz, *History of Black Fire*. <http://footguards.tripod.com/06ARTICLES/ART28blackpowder.htm>. V. Christides et al. (eds.) (2004). *Treasures of Arab-Byzantine navigation (7th–13th c.)*. Athens: IGOAS, p. 45)

300 °C (572 °F) and it is easily lit by a flame. A Chinese illumination depicts a soldier ready to launch a fire arrow igniting a rocket (Fig. 6). According to Haw (2013), “each Chinese soldier [specialized in pyrotechnics] carried a small iron pot containing fire to light the lance.” Most probably the Arabic rocket was also similarly ignited.

Such propel rockets could have been mounted on Arab warships following Chinese naval practices. The Chinese developed various types of explosive carrying warships after the tenth century. It is not, therefore, surprising that the Arabs acquired some important Chinese inventions concerning the construction of warships carrying Greek fire and other explosives, known as “burlot type.” There were various vessels of the burlot type in China after the tenth century. One of them (*lianhuanzhon*) was divided into two parts; the first loaded with firebombs was attached to the enemy while the second was detached and then withdrawn (Fig. 7). Another swift vessel (*chilonghuan*), full of explosives, was moved by four oarsmen who, after attaching it to the enemy ship, immediately abandoned it and retreated swimming. The existence of similar Arabic vessels is clearly manifested in a depiction of a -rocket-propelled torpedo in Ḥasan al-Rammāh’s abovementioned manuscript.

In conclusion, it should be noted that in spite of a number of Byzantinists who still hold the false impression that Greek fire was a secret Byzantine weapon, the primitive propel rocket

Rocket Machinery of the Mamluks, Fig. 7

A Chinese burlot is depicted loaded with firebombs carried on lances (Photo courtesy of Prof. Zhang Jun-Yan, Peking University)

described in the Arabic sources adds one more piece of evidence for the successful use of incendiary weapons by the Arabs, especially at the time of the Mamluks. Actually, the Mamluks who, in spite of their original indifference towards naval warfare, managed at the turn of the fifteenth century to develop an important navy although it was short lived (Christides, 2009) must have also used their newly discovered naval weapons.

Finally, it should be mentioned that the Byzantines also developed portable fire throwers which are laconically mentioned in Leo VI's *Naumachica* (Pryor & Jeffreys, 2006, p. 508), while there is also pictorial evidence of Byzantine movable hand siphons in land war (Zouache, 2008, p. 801). More research is needed to illuminate this neglected aspect of late Byzantine technology.

Rockets in Ancient Korea

Chae Yeon-Seok

The development of Korean rockets as tactical weapons began in the late fourteenth century. According to *Koryo Sa* (The History of the Koryo Dynasty) and *Cho Son Wang Cho Silok* (The Historical Records of the Choson Dynasty),

Rockets in Ancient Korea, Fig. 1 Drawings of *Hwa-Jeon* (a) Fire arrow (*Ju-Hwa*) (Drawing from *Kuk Cho Ore Sorye* 1474). (b) Fire arrow (*Hwa-Jeon*)

(Drawing in metric units (from Chae 1981)). ①: arrow shaft, ②: arrowhead, ③: black powder, ④: fins

King Wu (1377–1389) of the Koryo dynasty (918–1392) ordered the establishment of the Hwa-tong-do-gam (General Bureau of Gunpowder Artillery) in 1377 on the recommendation of Choi, Mu-Son (1325–1395). Commissioned temporarily at the height of Japanese piracy, the Bureau was charged with administering the manufacture of gunpowder and firearms.

Choi, Mu-Son produced a variety of gunpowder and firearms in the newly commissioned Bureau. Fire arrows, called *Haw-Jon*, manufactured at Hwa-tong-do-gam between 1377 and 1391 near the end of Koryo Dynasty were not, unlike some Chinese counterparts, rocket-propelled arrows but exclusively incendiary arrows. They were shot with a bow. Figure 1a illustrates the fire arrow as described in *Kuk Cho Ore Sorye* (Introductory Remarks on National

Rituals/Formalities of National Functions) of the Chosun Dynasty (1392–1910) published in 1474. Figure 1b shows a drawing of fire arrows in metric units converted from the Korean measurement system in which one *chuck* corresponds to 312.4 mm, one *chun* to 31.2 mm, one *pun* to 3.1 mm and one *le* to 0.3 mm.

Unfortunately there is no direct documentary evidence attesting that firearms manufactured at Hwa-tong-do-gam involved rocket-propelled firearms. However, *Kuk Cho Ore Sorye* contains illustrations of rocket-propelled firearms called *Sin-Gi-Jeon*. Moreover, *Hwa Po Sik Un Hae* (Korean Annotation of Gunpowder and Firearms Method, 1635) makes reference to the identity of the propellant cases of *Sin-Gi-Jeon* and *Ju-Hwa* (running fire), a term used for rocket-propelled arrows of the Koryo Dynasty. It is inferred from these historical records

that the *Ju-Hwa* manufactured at Hwa-tong-dogam was the first Korean rocket.

According to *Kuk Cho Ore Sorye*, the arrow shaft of the *Ju-Hwa* is made of a ► **bamboo** stick, and the arrowhead is iron. The tail fins of the arrow are feathers. Although there is neither a direct nor detailed description attesting that *Ju-Hwa* was rocket-propelled, that may be inferred from other historical records. *Choson Wang Cho Silok* records King Sejong speaking to an official PyeongAn, in HamGil province:

Running-fire is very efficient and incomparable because it can be fired easily using a quiver by a mounted soldier. It is detrimental to the enemy; its loud noise and shape instill fear and incite surrender. Once used at night, its exhaust flame lightens the fields and shakes the enemy's spirits.

When used where the enemy is lying in ambush, its flame and smoke cause the enemy to disclose themselves for fear. Running-fire does not fly straight and it spends more powder and requires more precaution than cannon.

"Its loud noise and shape," implies a propulsive device which produces thrust by ejecting combustion gases and thus produces the loud noise. "Once used at night, its flame lightens the field," excludes the possibility that *Ju-Hwa* was a cannon or rifle as it produced "flame and smoke" during flight. In addition, the motion of ancient rockets does not generally follow a straight line because it depends on stabilizing sticks made of bamboo with an exhaust hole in the powder charge in the propellant case. Most of the weight of a solid-propellant rocket is due to the propellant. *Ju-Hwa* "spends more powder" than a gun or cannon as it continues to eject combustion gas in flight.

According to *Hwa Po Sick Eon Hae*, the medium running fire was charged with 41.4 g of black powder. Extrapolating the weights of small and large running fires from the weight of the medium-sized running fire and proscribed volumes of propellant cases of the small and large running fire, the weight of small and large running fire is given by 12 and 2,628 g, respectively. The weight of black powder for a large running fire is significantly larger than that of the

Rockets in Ancient Korea, Table 1 Powder charge of rockets and cannons in fifteenth century Korea

Rockets		Cannon and guns	
Name	Powder weight	Name	Powder weight
Large running fire	2,628 g	Chun Ja Chong Tong (General cannon)	870 g
Medium running fire	41.4 g	Dae Wan Gu (Large motor)	870 g
Small running fire	12 g	Sung Ja Chong Tong (Victory letter gun)	26.7 g

largest cannon used in fifteenth century Korea with the black powder weight of 870 g (Table 1).

Korean Rockets of the Fifteenth Century

The reign of King Se Jong (1418–1450) of the Choson dynasty marked a turning point in the development of firearms, moving beyond the imitation of Chinese models and creating a distinctive Korean model. In the 30th year (1448) of the reign of King Se Jong the details and manufacturing methods of firearms and ready-to-launch munitions were compiled, illustrated and published in the *Chong Tong Deong Rok* (Reproduced Records of Firearms and Gunpowder). No copy of *Chong Tong Deong Rok* had survived, but part of it is in *Kuk Cho Ore Sorye*.

According to *Hwa Po Sik Eon Hae*, three types of rocket-propelled arrows were in wide use in their mature form by the 29th year (1447) of King Se Jong's reign: large, medium, and small running fires. In *Choson Wang Cho Silok*, such firearms are no longer mentioned by those names after 1448 and onward, but instead a new set of names of firearms begins to appear, namely *Sin-Gi-Jeon*, literally meaning "magical machine arrow." However, the specifications and manufacturing methods of the medium-sized *Sin-Gi-Jeon* described in *Hwa Po Sik Eon Hae* are identical to those for the *Ju-Hwa*. Thus, it is inferred that the *Sin-Gi-Jeon* was based on the *Ju-Hwa* and developed further to include versions of various sizes: small (*So*), medium

Rockets in Ancient Korea, Fig. 2 Large magical machine arrow (a) Propellant case from *Kuk Cho Ore Sorye*, 1474. (b) (Drawing in metric units). ①: warhead, ②: propellant case, ③: bamboo, ④: fins

(*Chung*), large (*Dae*), and multiple bomblets magical machine arrows.

Dae-Sin-Gi-Jeon (Large Magical Machine Arrow)

Figure 2 shows a drawing of the *Dae-Sin-Gi-Jeon* (large magical machine arrow) in the *Kuk Cho Ore Sorye*, and a drawing reproduced in metric units. The propellant case filled with black powder is a cylindrical tube made of paper. It is 695 mm long, 17.8 mm thick, and the internal diameter is 63.1 mm. Both ends of the propellant case were sealed with paper several times and attached to the front end of the ► bamboo shaft by strings. At the bottom end of the propellant case, opposite the warhead, a hole was made to allow exhaust fumes to exit. The bamboo shaft is 5.3 m long with the cross-sectional diameter increasing from 10 mm at the front to 29.5 mm at the rear. At the rear of the bamboo shaft three feathers were evenly distributed in between. The “Firearms Illustration” in *Kuk Cho Ore Sorye* records that they are bird feathers. However,

there is no feather of size 30×840 mm, and it is reasonable to conjecture that they were made of leather, considering that arrows fired from a cannon at that time were equipped with feathers made of leather.

An explosive tube is mounted on the front end of the propellant case. A detonating fuse extends from the explosive tube through a hole made on the surfaces of the explosive tube and the propellant case into the propellant case. Such an arrangement enabled the explosives to detonate during or near the end of the flight to the target. The overall length of the *Dae-Sin-Gi-Jeon*, including the explosive tube, reached 5.6 m. *Dae-Sin-Gi-Jeon* was primarily used to launch an offensive on enemies across the Apruk river at its estuary from Eui-Ju City. Considering the width of the estuary, the *Dae-Sin-Gi-Jeon* is surmised to range from 1.5 to 2 km.

The *San-Hwa-Shin-Gi-Jeon* (Fire scattering magical machine arrow), an application of *Dae-Sin-Gi-Jeon*, was also used. Instead of employing the explosive tube of *Dae-Sin-Gi-Jeon*, the front

Rockets in Ancient Korea, Fig. 3 Image of large magical machine arrow

part of the propellant case was occupied by a bundle of paper explosives called *So-Bal-Hwa* (small fire burner) connected by a detonating fuse. *San-Hwa-Sin-Gi-Jeon* was designed to disperse paper explosives ignited when they were near the target.

Dae-Sin-Gi-Jeon is the largest rocket ever made employing explosive cases made of paper, and a reproduced version is shown in Fig. 3. It was 350 years later that rockets of comparable size were manufactured elsewhere; in 1805 William Congreve of England produced 6-pound rocket with a propellant case 550 mm long, a diameter of 110 mm and an overall length including stabilizing sticks of 4.3 m.

Medium and Small Magical Machine Arrow (*Chung- and So-Sin-Gi-Jeon*)

The *Chung-Sin-Gi-Jeon* (medium magical machine arrow) has a 1.4 m long bamboo shaft with a 200 mm long propellant case attached to

the front. An arrowhead weighing 5.5 g is fixed at the front end of the *Chung-Sin-Gi-Jeon*, and at the rear end are attached 17.8 cm long bird feathers. There is no mention on the range of *Chung-Sin-Gi-Jeon*, but it is estimated to range from 150 to 200 m.

A detailed drawing showing the internal structure of the medium magical machine arrow is reproduced in Fig. 4. The lower part of the propellant case is bound with twine as in the large magical machine arrow. The propellant case is charged with powder up to the height of 175 mm leaving an empty space with a corresponding height of 25 mm. A small explosive tube (*so-bal-hwa-tong*) 56.2 mm long, 47.8 mm in circumference, 4.4 mm thick and 6.9 mm in internal diameter is inserted into the propellant case. The length from the end of the cylindrical case to the attachment twine is 6.3 mm, and the diameter of the nozzle is 2.2 mm. Finally, the powder in the propellant case of the medium magical machine arrow was connected with fuses.

The *So-Sin-Gi-Jeon* (small magical machine arrow) is the smallest version of the series as shown in Fig. 5. Its propellant case, 15 cm long with a cross-sectional diameter of 15 cm, is attached to the front of a 100 cm-long bamboo shaft. At the rear end bird feathers are attached. The diameter of the exhaust hole installed in the propellant case is 4 mm, and the range is estimated to be about 200 m. Figure 6 shows pairs of reproduced running fire, and small and medium magical machine arrows reproduced in 1979.

Multiple Bomblets Magical Machine Arrow (*San-Hwa-Sin-Gi-Jeon*)

The multiple bomblets magical arrow is similar to the large magical machine arrow in size, but it differs in the warhead system. A propellant case serves as a warhead instead of an explosive tube.

The detailed internal structure of the propellant case and explosive system of the multiple bomblets magical machine arrow is shown in Fig. 7. The lower part of the propellant case was bound with twine as in the large magical machine arrow. The propellant case was charged with powder up to the height of 579.5 mm, leaving an empty space corresponding to the height of

Rockets in Ancient Korea, Fig. 4 Medium magical machine arrow. (a) (Drawing from *Kuk Cho Ore Sorye*, 1474). (Drawing in metric units). ①: warhead, ②: propellant case, ③: bamboo, ④: fins

Rockets in Ancient Korea, Fig. 5 Drawing of small magical machine arrow in metric units

115.6 mm. Several layers of paper were attached to the top surface of the powder. Several land fire tubes (*Ji-Hwa-Tong*) attached to small explosive tubes (*So-Bal-Hwa-Tong*) were placed on the top of the propellant case with their fuses attached to the propellant charge.

The “Firearms illustration” section of the *Kuk Cho Ore Sorye* provides detailed explanations on manufacturing arrows, including charging propellant cases. A long, coned-shaped awl was

inserted through the hole in the bottom of the propellant case. Then a small quantity of powder was spread and hardened with an empty cylindrical iron stick with its external diameter equal to the internal diameter of the propellant case.

Rocket Launch Device: Hwa-Cha (Fire Cart) and Launch Pad

The structure of the launch pads for rockets is relatively simple, since it primarily serves the

function of providing a direction to the target. Even now, launch pads of rocket cannons retain such simplicity, resembling a piece of a chimney.

During the reign of King Moon Jong (1450–1452), proper launch pads were developed for the *Sin-Gi-Jeon*. King Moon Jong himself was

interested in the development of firearms. When he was a crown prince he assumed some responsibility at the Bureau of Weapons. He also played a pivotal role in developing a *Hwa-Cha* (fire cart). *Hwa-Cha* could be loaded either with a launch pad capable of launching 100 *Sin-Gi Jeon* in sequence or with a gun tube pad capable of launching 200 *Se-Jeon* (bullets). Figure 8 shows a drawing of the fire cart in *Kuk Cho Ore Sorye* and a drawing reproduced in metric units.

The most notable feature of the *Hwa-Cha* is that the inclination of the launch pad was variable. The general feature of carts up to the reign of King Se Jong was to load a launch pad on the axle of the wheel. However, the car invented during the reign of King Moon Jong employed a column on and in the middle of the axle of the wheel, which enabled the launch pad to be inclined up to 40°. The first *Hwa-Cha* was dispatched in 1,451, and in the same year 700 additional carts were soon dispatched to strategic coastal regions and fortresses. During peace time *Hwa-Cha* served as wagons.

The diameter of the wheel is 874.7 mm. The hub is made of wood, 225 mm wide and 206.2 mm in diameter. Each wheel has 15 spokes. The spindle on which the wheels revolve is made of wood, 1,312.1 mm long, and consists of three parts: a middle square pillar and two end columns which are inserted into two wheels. Two wide posts are set up at both ends of the top side of the middle square pillar. A small post is set up at

the center of the square pillar. Thin wooden boards are attached between each wide post. Two yokes are set up at both ends of the wide posts. An upper center crossbar is placed between the ends of both wide posts. It has a hole in the center for the small post. A rear crossbar is attached at the rear of (four-cornered part) of both yokes. Several thin wooden crossbars are attached between the rear crossbar and the upper center crossbar. This forms a wooden box to hide some arms. Its length and width are 624.8 and 515.5 mm.

Four U-shaped nails are driven into the front and middle of the column part of the yokes to insert rods, which are used to pull the fire cart. Two men could draw the cart on level ground, but it would require another man pushing from behind going uphill, and two more men had to push the cart when it was going up a steep hill.

Figure 9 shows a drawing of the launch pad for magical machine arrows based on the

descriptions in *Kuk Cho Ore Sorye*. It consists of a rectangular box containing blocks with 100 cylindrical holes and a supporting mechanism. They are comprised of seven rows of blocks. The end of each block is pierced with a wire and both ends of the wire are attached to the external surfaces of the side boards of the rectangular box. The supporting mechanism houses the rectangular box and consists of a set of columns and crossboards. The first crossboard is 1,171.6 mm long, 109.3 mm wide, and 47 mm thick. It has a 62.4 mm diameter hole in the center into which the small post of the fire cart is inserted. The main body of the launcher is supported by two columns, small square columns, and assistance columns.

The design of the fire cart and the magical machine arrow launcher enabled the cart body to be raised above the axle by short pillars to regulate the angle from 0 to 43°. The magical machine arrow launcher when fully loaded could launch

Rockets in Ancient Korea, Fig. 11 Flight test of small and medium *Sin-Gi-Jeon* at Daejeon Expo 93

100 medium or small magical machine arrows in groups of 15 at a time. According to the *Moon-Jong-Silok*, 700 fire carts were built in Korea in 1451. Figure 10 shows a version of a fire cart and launch pad loaded with small and medium magical machine arrows reproduced in 1979.

The first Korean rocket manufactured in Hwa-tong-do-gam between 1377 and 1389 provided the technological heritage for forthcoming rockets called *Sin-Gi-Jeon*. *Kuk Cho Ore Sorye* served as a technical manual for manufacture and operation of the rockets. While the large *Sin-Gi-Jeon* is the largest rocket ever made amongst those employing a propellant case made of paper in the fifteenth century, the use of the unit of length “le” corresponding to 0.3 mm demonstrates that *Sin-Gi-Jeons* were manufactured with a considerable level of precision. Historical records attest that 33,000 or so running fires and magical machine arrows were maintained in Korea by 1447, and dispatched for action with the fire cart from 1451. These weapons are

believed to have served as powerful weapons for raiding Chinese and Japanese bandits.

Unfortunately, neither the *Sin-Gi-Jeon* nor the fire cart survives, primarily because they were made of wood and paper. In order to verify the technical feasibility of drawings and manufacturing methods in *Kuk Cho Ore Sorye*, small and medium *Sin-Gi-Jeons* were reconstructed together with their fire carts and launch pads for a flight test at the Daejeon Exposition in 1993. Figure 11 depicts the moment of the flight test of 100 small and medium *Sin-Gi-Jeons* in 1993. The *Sin-Gi-Jeons* traveled between 100 and 200 m in distance. The successful test cleared the obscurity surrounding the rockets which had arisen from the fact that there were no remaining models; it demonstrated that they were nearly flawless in terms of design and function.

Rockets in China

Pan Jixing

Traditionally, a rocket is a flying device launched by direct-reaction using a solid black powder of high-nitrate composition. The appearance of rockets signified a revolution in the development of firearms. All modern rockets were gradually developed on the basis of traditional ones. In Ancient China the rocket was generally called *huojian* (fire-arrow) which sometimes meant incendiary arrow and sometimes rocket. Both of

them were invented in China. It is necessary to differentiate one from the other. From 968, the classical fire-arrow was sent by low-nitrate ► [gunpowder](#) in paste form from a bow or cross-bow. It was thus an incendiary arrow, although it was the earliest gunpowder weapon. Since the beginning of the twelfth century solid gunpowder of high-nitrate composition and fuses were made and used for making fireworks and firecrackers. Some of them were directional devices, such as the *di laoshu* (earth-rat), *qihuo* (flying fire), and others. This provided a necessary premise for making rockets. During 1127–1234 the invention and military use of rockets were perfected in China on the basis of fireworks technology. There were two types of early rockets having different names.

The so-called *pili pao* (thunder-bolt missile) used in the Battle of Caishi between the Song and Jin was actually the earliest rocket-propelled bomb in the world. It was an enlarged *ertijiao* (double-bang firecracker) and was made according to the principle of *qihuo* (flying fire) used by the Song people in an earlier time. The *fei huojian* (flying fire-lance) used in the Battle of Kaifeng between the Jin and Mongols in 1232 was an ordinary rocket for setting things on fire. Its rocket tube made of paper was fastened to the point of a lance or an arrow. During the thirteenth to fourteenth centuries the Song, Jin, and Mongol troops all used improved rockets to fight with each other. They even used the reaction weapon abroad. For instance, single rockets and multiple rocket-launchers with a common fuse were used by the Mongols in the Battle of Leignitz in Poland in 1241, known as the “Chinese dragon belching fire” in the West. Winged rockets must have been made in about 1300, since it was described in the *Huolong Jing* (Fire-Dragon Manual, ca. 1350).

In the Ming dynasty (1368–1644) rocketry entered a new epoch. Two-stage rockets were designed and made at the beginning of the fourteenth century. There were various kinds of different rockets from single ordinary ones to multiple rocket-launchers and wheelbarrows, as well as winged rockets and rocket-propelled bombs. Their range reached 200–500 paces (330–825 m). There was a special rocket troop

in the Ming army and rocket weapons were used as standing weapons by land and naval forces and cavalry troops. It is interesting that a Chinese military officer, Wan Hu (fl. 1440–1495), built a flight device made of 47 big rockets for a flight experiment. He was the first in history to try to use rockets for flight as a means of transportation. All of these ancient achievements in the field of rocket technology can be found in the military work entitled *Wubei Zhi* (Treatise on Armament Technology) written by Mao Yuanyi (ca. 1570–1637) in 1621. After rocket technology was perfected in China it was spread to other parts of the world. It went first to the Arab world in 1240–1260, then to Europe in 1260–1270. The term *rochetta* first appeared in Italian literature in 1330. In the eighteenth century rockets were popular in some major European countries. Rockets arrived in other Asian countries in the same time during the Mongol-Yuan period, first in Vietnam and Korea, then in India and Southeast Asia.

In 1805 the British military officer William Congreve (1772–1825) developed modern rockets made of iron tubes with black powder, which had a range of 2,300 m. But after the mid-nineteenth century rocketry ceased to develop, because modern cannons seemed to be more powerful and effective. Since the beginning of the twentieth century rockets have been given more attention and studied carefully. As a result, various new types of rockets have been developed and used, especially since World War II. Joseph Needham says:

In this day and age, when man and vehicles have landed on the moon and when the exploration of outer space by means of rocket-propelled craft is opening before mankind, it is hardly necessary to expatiate upon what the Chinese started when they first made rockets fly.

Rockets in India

Roddam Narasimha

Engineering Mechanics Unit, Jawaharlal Nehru
Centre for Advanced Scientific Research,
Bangalore, India

Introduction

Fire arrows in some form have been known for thousands of years in several cultures (*agni-bāṇa* in Sanskrit). In contrast to arrows (even fire tipped) which are shot with the help of the stored elastic energy of a bowstring, rockets are entirely self-propelled, usually by conversion of the chemical energy stored in the propellant(s).

It is generally agreed that rockets were in use in China in the eleventh century CE, perhaps in the form of what we might now term a “rocket-assisted arrow”; over time the arrow came to be discarded as the rocket became sufficiently powerful to serve as a destructive warhead by itself. In 1232 CE, five years after Genghis Khan's death, Chinese rocket barrages repeatedly repulsed Mongolian cavalry led by his successors in attacks on the city of Kaifeng (which nevertheless fell in 1233; Grousset, 1965). The invention traveled rapidly (presumably through the Mongols) to Europe, where it was first mentioned in 1258 CE and was experimented with and used up to the fifteenth century: in England Roger Bacon (1214–1294) had worked on both advanced gunpowder and rockets. However, towards the beginning of the sixteenth century, the cannon (invented around 1300 CE) had improved so much that the military rocket fell into disuse, although it survived as a part of festive pyrotechnics.

In India rockets had been occasionally used by the Moghuls (Qaisar, 1982) and in a small way by the Nawab of Arcot in the south (Forrest, 1970) during the first half of the eighteenth century. The reemergence of the rocket as a significant military weapon occurred during the second half of the eighteenth century in the princely state of Mysore in south India. To understand the historical context in which this development took place, a brief appreciation of the political/military situation in eighteenth-century India is necessary (see map, Fig. 1). Following the collapse of the Moghul Empire early in the century, power began to shift to numerous regional rulers or adventurers, comprising (in the South) the Marathas, the Nizam of Hyderabad, the Rajas of Mysore and Travancore, and the Nawab of Arcot (Carnatic). Early in the century the Wadiyar dynasty in Mysore had become weak, and power was virtually handed over in 1760 to Hyder Ali (1720–1782), the illiterate but dynamic great grandson of a Sufi peer who had migrated southwards from Punjab in the North (Wilks, 1810). Hyder had entered service with the Commander of the Mysore Raja's forces in 1749 and, by sheer dint of his military and political ability, rose quickly to the position of Sarvadhikari (Supreme Officer, and for all practical purposes the Ruler) with the Wadiyars in 1760. (He must have been aided by a syncretic and tolerant Sufi philosophy that did not consider matter and spirit as distinct entities and was largely acceptable to both Hindus and Muslims.) Hyder was succeeded in 1782 by his son Tipu Sultan (1750–1799), who became the de facto ruler of Mysore. The Hyder-Tipu half-century coincided with the rise of British power in Bengal and the South, and the East India Company (EIC) became a new player on the South Indian chessboard. The nature of the company's power – military, political, administrative, technological, and intellectual – was correctly assessed by Tipu (Fig. 2) – and perhaps only by him among all the Indian rulers of the time.

The development of the rocket in Mysore, and its use in the conflict with EIC in the four Anglo-Mysore wars (respectively, in 1767–1769, 1780, 1792, and 1799), is a fascinating episode in the history of technology – not only in India but the

Rockets in India,

(Joppen, 1920)

R

world. It is the purpose of this essay to narrate how this happened and the interesting sequel of its immediate development and industrialization in nineteenth-century Britain. We shall however touch only briefly on how the rocket spread to the rest of Europe including Russia, and to the USA and elsewhere in the world, during the twentieth century. The use of military rockets in the Anglo-Mysore wars thus provided the direct trigger for the spectacular developments that have taken place in the last two centuries and are continuing globally to do so even now.

Much of the material presented here is taken from Narasimha (2012); it is part review and part

update of the author's work on different aspects of the subject of the essay, as contained in the three references cited at the end. New material is introduced especially in sections "[Construction, performance, and use of the Mysore rockets](#)" and "[Tipu's character](#)."

Construction, Performance, and Use of the Mysore Rockets

The rockets used by the Mysoreans consisted of a metal cylinder (casing) containing the combustion powder (propellant), tied to a long

Rockets in India, Fig. 2 Tipu Sultan (Cover page, March of Karnataka 1999, Vol. 37, Government of Karnataka)

bamboo pole or sword which provided the required stability to the missile (Fig. 3). There is a recognizable resemblance to the familiar but much smaller pasteboard “rockets” one can see during fireworks in India and elsewhere to this day. Unfortunately there is little authentic technical documentation available in India about these rockets, as they were the work of artisanal communities that jealously guarded knowledge accumulated over generations (Narasimha, 2003) and kept it from becoming public in any way. The last of the three factories that had at one time made “real” war rockets at Tipu’s capital Srirangapatana (Seringapatam) was destroyed in an explosive fire in the early 1960s (according to Stripp, Bhogle 1991), making it too late now to construct even a reliable oral history. Much of our information about the rockets come therefore from early British accounts, dating back to the last decades of the eighteenth century. Useful summaries are available in Ley (1958), Von Braun and Ordway (1966) (referred to in the

sequel as L and vBO, respectively), and Baker (1978).

Two specimens, fortunately preserved in the Royal Artillery Museum, Woolwich Arsenal, have these dimensions (vBO, see Fig. 3):

- (i) Casing 2.3 in. O.D. $\times$ 10 in. long ($\sim$ 58 mm O.D. $\times$ 254 mm long), tied with strips of hide to a straight 3 ft. 4 in. ($\sim$ 1.02 m) long sword blade
- (ii) Casing 1.5 in. O.D. $\times$ 7.8 in. long ($\sim$ 37 mm O.D. $\times$ 198 mm long), tied with strips of hide to a bamboo pole 6 ft. 3 in. ($\sim$ 1.9 m) long

The propellant was gunpowder. The real advance in technology of these rockets over the state of the art in Europe was in the material of the casing, which was a metal cylinder made of hammered soft iron. European rockets of the time had combustion chambers made of some kind of pasteboard; e.g., Geissler in Germany used wood, covered with sailcloth soaked in hot glue (L). In the eighteenth century iron was still generally of much better quality in India than in Europe, as we shall discuss further below. The use of iron increased bursting pressures, permitting the propellant to be packed to greater densities. This gave the Mysore rockets a higher thrust, and hence also longer range, as later confirmed by tests in England as about 1,000 yards, approximately twice that of the most powerful European rockets of the time (see section [Tipu’s Character](#)). There are however other accounts (e.g., L) that speak of rockets generally weighing 3.5 kg, tied to 10 ft ($\sim$ 3 m) bamboo poles, and with a range of up to 1.5 miles (2.4 km): this was an “outstanding performance for the time” (Baker, 1978).

Incidentally, the superior characteristics of the iron used for the casing is not such a surprise, as ferrous metallurgy in India has a history that can be traced as far back as the middle of the second millennium BCE (Tripathi, 2008). In the Mysore area (Karnataka today) the earliest site has been dated to 1440 BCE. Premodern iron-smelting sites in South India occur in two clusters, of which the bigger runs north to south, from today’s south Andhra Pradesh (Telangana) through east Karnataka to northern Tamil Nadu.

Rockets in India,

Fig. 3 Replicas of the rockets used by Tipu's troops. *Top*: rocket with stabilizing blade; *bottom*: rocket chamber

A famous Mysore site in this “iron belt” was Chitradurga, which during Tipu’s times was one of the four specially selected industry centers called Taramandalpets (roughly translating to galaxy or star-cluster bazaars), which were Tipu’s “technology parks.” It is easy to imagine that the iron technology so easily available in Mysore was a major factor in the development of the casing of Tipu’s rockets. The steel from these and other Indian sites, especially the kind called wootz (derived from the Kannada word *ukku*, according to the Oxford English Dictionary), was used in the celebrated Damascus swords; it has been called “the first high-quality steel made anywhere in the world” (Verhoeven & Pendray, 1998, cited in Srinivasan & Ranganathan, 2004). Some Indian iron and steel was still being imported by Britain in the early nineteenth century (Tripathi, 2008).

The use of rockets by Hyder and Tipu is mentioned at various places in Wilks’s (1810) famous *History of Mysoor*. A recent, readable account of

the history of Tipu is Forrest (1970). There was a regular Rocket Corps in the Mysore Army (Fig. 4 shows a typical rocket-man), with about 1,200 men in Hyder’s times, growing to about 5,000 in Tipu’s army. In the Third Anglo-Mysore War of 1792, there is mention of two rocket units fielded by Tipu, commanded, respectively, by Qamar-ud-din Khan (120 men) and Purniah (131 men). Qamar-ud-din was a cousin and a favorite general of Tipu and Purniah the famous Hindu *dewan* (chief minister) who served the Maharajas of Mysore, Tipu, and the British through a time of rapidly fluctuating fortunes. Wilks mentions the skill of the rocketmen (see also Forrest, 1970) in selecting the elevation to suit the varying dimensions of the cylinder and the required range. Furthermore, the rockets could be launched rapidly using a wheeled cart with three or more rocket ramps. Other accounts speak of how Tipu’s rocketmen threw a “great number of rockets at the same instant” (vBO). Then there were the so-called ground rockets

Rockets in India,

Fig. 4 One of Tipu's soldiers, using as flagstaff the kind of rocket employed by the Mysoreans in 1792 (Source: Buddle, 1990)

which, “on striking ground, would rise again and bound along in a serpentine motion until their force was spent.”

British Reactions to Mysore Rockets

In most histories of the Anglo-Mysore wars, the use of rockets by the Mysore armies is frequently mentioned, often in association with muskets. Apart from Wilks and Forrest, we can cite Rao (1943), Kirmani and Mir Hussain Ali (1864), and Dirom (1793), among others. “Rockets and musket fire” appear almost casually in such accounts, indicating how widespread the use of rockets must have been. We shall briefly describe some specially striking military events involving Mysore rockets.

The Battle of Pollilur

This was fought on 10 September 1780 during the Second Anglo-Mysore War (Wilks, 1810): Pollilur is a small village between Kanchipuram and Arakkonam in today's Tamil Nadu. In July of

that year, Hyder, with 80,000 men and 100 guns, [had come] down upon the plains of the Carnatic (see map Fig. 1), “like an avalanche, carrying destruction with him” (Majumdar, Raychaudhuri, & Datta, 1958). Hyder and Tipu achieved a famous victory at Pollilur, and it is widely held (e.g., Forrest, 1970) that a strong contributory cause was that one of the British ammunition tumbrils was set on fire by Mysorean rockets; the scene is celebrated in a famous mural (Fig. 5) at Darya Daulat Bagh, Tipu's summer palace in his capital Srirangapatna. (An 1820 reproduction by an unknown Indian artist may be seen in the National Art Gallery at Edinburgh, Fig. 5.) Writing about this war, Sir Alfred Lyall remarked, in *Rise and Expansion of the British Dominion in India* (1914), “The fortunes of the English in India had fallen to their lowest watermark” (Majumdar et al., 1958).

Accounts of the use of rockets in the Second Anglo-Mysore War appeared in a book by Innes Munro titled *A narrative of the military operations on the Coromandel Coast* etc. etc., published in London in 1789. Munro had spent the period 1778–1782 as a correspondent of the *Times* accompanying British troops on their various campaigns in South India.

The Sultanpet Incident

During the Fourth (and final) War, rockets were again used on several occasions. One of these involved Col. Arthur Wellesley, to become famous later as the Duke of Wellington and hero of Waterloo. The incident is therefore of some special interest – not so much because of its impact on the war as of the light it throws on the psychological effects of a totally unforeseen encounter with the rocket in battle on British officers and men of the East India Company.

On the night of 5 April 1799, just before the impending siege of Srirangapattana, Wellesley was chosen as commander for an operation whose objective was to clear a *tope* (grove) which gave shelter to Tipu's rocketmen. The *tope* was near Sultanpet (or Sultanpettah), and what happened there is vividly described by Philip Guedalla in his biography of the Duke of Wellington (Guedalla, 1940). As Wellesley's

Rockets in India,

Fig. 5 Part of a mural celebrating the victory of Hyder and Tipu in 1780 over the British in Pollilur. Col. Baillie is seated in a palanquin in the middle of a square formed by British troops. An ammunition tumbril on the top left corner of the square is seen to have caught fire, by a rocket attack from Mysore rocketmen according to several reports. The mural decorates a wall at the Darya Daulat Bagh in Srirangapattana, but the image here is from a reproduction made by an unknown Indian artist in 1820, now in the possession of the National Gallery of Art at Edinburgh (Buddle, 1999)

column advanced from his camp towards the *tope* in pitch darkness, it was attacked all of a sudden by heavy musket fire and rockets. According to a report of Hook (1833) cited by Rao (1943), “the men gave way, were dispersed and retreated in disorder. Several were killed, and twelve grenadiers (these men were all murdered a day or two before the storm) were taken prisoners.”

A spent ball had struck Wellesley on the knee, and he left his men (in Guedalla’s words) to “report his failure... reeled back to camp ... and the exhausted man, his nerves all frayed, flung himself face down across the mess-table to sleep.” Wellesley’s behavior was sufficiently serious to give rise to talk of a possible court-martial. The “Sultanpet” incident clearly had a traumatic effect on Wellesley, for he used to come back to the incident even late in life, with his own explanations of what happened and why. At the same time, according to Guedalla, the incident was what converted Wellesley to transforming himself to a man with “nerves of steel,” the future “Iron Duke.”

Other British Responses

One account, from a young English officer named Bayly (cited by vBO) said: “The rockets and musketry from 20,000 of the enemy were incessant. No hail could be thicker. Every illumination of blue lights was accompanied by a shower of rockets, some of which entered the head of the column, passing through to the rear, causing death, wounds, and dreadful lacerations from the long bamboos of twenty or thirty feet, which are invariably attached to them.

To balance these was a report by a British “observer” (also cited by vBO), according to whom the rockets were very noisy and annoyed Indian cavalry (this observation seems doubtful as Tipu’s cavalry was used to rocket fire), but that they had less effect on British troops which were organized along the famous thin [“red”] lines (see Fig. 5), whose lack of depth saved them.”

[Incidentally the dates quoted in vBO for some events in the Anglo-Mysore wars are inconsistent with other reports and have therefore been corrected as proposed by Narasimha (2012).]

For the purposes of this essay, the main conclusion we draw is that these accounts leave no doubt that the rocket was a totally unfamiliar weapon to the Company's troops and its commanders, and whatever its military effectiveness might have been, its psychological impact was extraordinary even on seasoned European troops of the time.

Tipu's Character

The story of the Mysore rockets would not be complete without a few remarks on the character of the man who was chiefly responsible for the rocket program.

First of all Tipu (who was named after a Muslim saint) was a Sufi warrior. As a child he had two teachers, one Muslim and one Hindu. The syncretic religious environment that prevailed in South India was possible because of the close similarities in both Hindu and Sufi-Muslim views of sacred power, in particular of *śakti* and *barakat*, respectively, as analyzed by Brittlebank (1997). Tipu gave generous gifts to various Hindu temples and religious institutions and sought their prayers for his victory in battle. All this gave his rule a legitimacy and acceptability among most sections of the people of Mysore and a loyalty that went beyond the norms of the age in India. As Brittlebank (1997) argues, Tipu was gaining legitimacy in a largely Hindu state by following the popular Indic ideal of a universal king, without compromising his position as a devout Muslim. Tipu's treatment of his political opponents (of whatever religion) was however harsh, and this has led to several generally unjustified accusations of religious fanaticism, for he could also be surprisingly generous with people of other faiths under less threatening circumstances.

Secondly he was what today would be called a *technology buff*. According to a report cited by Wilks, Tipu's tent (in his besieged capital in 1799) housed "a very handsome case of instruments," and he possessed a library which contained "a translation of Euclid [into Farsi?],

several works of reputation on geometry, mathematics and astronomy." Even if (as the usually biased Wilks suggests) Tipu could not have practiced the mathematics, the very fact of Tipu's serious personal interest in such knowledge shows his keen appreciation of the importance of the contemporary science and technology of Europe. He may well have been the first Indian political/military leader whose response to the advent of the Europeans included a keen realization of the very significant advances that had been made by them in science, technology, administration, and discipline. Tipu was full of curiosity about European inventions such as barometers and thermometers and in turn gifted rockets to such notables as the Sultan of Constantinople (Rao, 1943). He was an enthusiastic patron of the technical arts and set up four special industrial zones called Tārāmaṇḍalpets, respectively at Srirangapattana, Bangalore, Bednur, and (as already mentioned) Chitradurga (Narasimha, 2003).

Finally he was a compulsive and indefatigable *innovator*. Wilks devotes a considerable part of one chapter of his book to discussing Tipu's "boasted improvements" and adopts an attitude of amused disparagement towards Tipu's numerous innovations, some of which were of course unsuccessful. But the range of Tipu's interests and his radical thinking were certainly singular for his time, look most impressive, and were often successful; apart from the rockets discussed here, we may cite the example of the introduction of sericulture: the "Mysore silk" that owes its origin to him is popular even today in India. Not only did his workshops make muskets, cannon, and other weapons but also glass, cutlery, paper, etc. His goal was what was called technological self-reliance or *swadeshi*, in the policy adopted by the new Indian government soon after the end of British rule in 1947; in this and other ways, he was ahead of his times. He was impatient and had a penchant for micromanagement. But his energy was extraordinary, and he did more for his state than any other prince did at the time for his own.

Rockets in India,

Fig. 6 Early rockets made by Congreve, beginning with copies of the Mysore rockets (with a typically blunt nose) and later with larger designs (with a typically sharp nose) (Congreve, 1827) (Source: Werrett, 2009)

Rocket Development in Britain

A vigorous program of what we would now call “research and development” on rockets took place in Britain beginning with the new century. There is no doubt that this interest in the rocket as a military weapon was inspired by the numerous reports from India, as well as the arrival of the Mysore rocket cases themselves in England (Baker, 1978). The ensuing development of rocket technology in Britain has been generally credited to Col. (later Sir) William Congreve, who was told (vBO) that “the British at Seringapatam had ‘suffered more from them [the rockets] than from the shells or any other weapon used by the enemy. . . . In at least one instance, an eye-witness told Congreve, a single rocket had killed three men and badly wounded others.’”

In 1801/02, Congreve bought (out of his own pocket) and tested the biggest skyrockets then available in London (L). Their range was found to be 500–600 yards, about half or less of that of the Mysore rockets. He then started developing his own, using the facilities of the Royal Laboratory at Woolwich Arsenal, with the support of such influential figures as his father who was Comptroller of the Laboratory and of Lord Chat-ham who was Prime Minister during 1783–1801.

Congreve first tested various combinations for propellant, made some rockets which were basically imitations of the Mysore rockets, and

eventually developed a rocket motor with a stout iron case 100 mm dia with a conical nose, weighing about 14.5 kg and attached to a 4.6 m long wooden stick 38 mm in diameter. Both of these early types are shown in Fig. 6.

In 1804 Congreve published a book titled *A concise account on the origin and progress of the rocket system* and claimed that his rocket’s “carcass is the largest of the kind that has hitherto been constructed for use,” obviously unaware of earlier European work, in particular the much larger rockets (with wooden casings, though) made by Geissler in Berlin in 1668 (L). Congreve’s rockets had iron hoops on one side, making it easier and quicker to fix the stabilizing stick, but later he also tried a configuration where the stick was fixed at the center of the casing with exhaust gases coming out of orifices around the circumference. By August 1906 he was reporting that 13,109 rockets had already been manufactured.

Although his program was directly inspired by the superior performance of the Mysore rockets, Congreve quickly thought of his program as one of developing “rational” rockets and a whole rocket *system*, implying that it was based on “philosophical” (i.e., scientific) principles (Werrett, 2009). Beginning with an application of Newton’s third law on action and reaction to understand rocket behavior, he recognized that one of the chief advantages of the rocket would

be the absence of the recoil force (“to ground,” so to speak) that made it so difficult to use cannon on ships. He therefore argued that rockets were particularly suited for seaborne assault, although he apparently came to feel later that this was not the best method of using them. He also experimented with a number of black powder formulas, set down specifications for their composition, standardized construction details, used improved production techniques (the stabilizing stick could be quickly inserted into hoops on the side of the casing and crimped), offered designs permitting either explosive (ball charge) or incendiary warheads (the former could be independently timed by trimming the fuse length before launching), studied the tactics of their use (recommending that they be fired in volleys of at least 20 and preferably 50 rockets once every 30 s, to compensate for their dispersion), and designed simple collapsible wooden frames to serve as launchers (dispensing with the heavy-wheeled carriages that were so necessary for transporting cannon and made them unusable in difficult terrain). Much of this work was clearly industrial in character.

A list of rocket types he developed, published by him in 1817, included seven rockets with carcasses varying from 12 to 42 lb and range varying from 2,000 to 3,000 yards. There were also flare rockets equipped with parachutes. And he also gave a detailed cost breakdown of the rockets, to contest the claim that they were too expensive. There can be no doubt that Congreve brought to rocketry ideas from the Newtonian science that had emerged a hundred years earlier, and the fruits of the industrial revolution sweeping Britain at the time.

However, as pointed out in Warrett’s interesting analysis, Congreve’s rational rockets “emerged at the same time as European attitudes to Eastern pyro-technics switched from reverence to disdain.” Congreve tried to introduce a “system” of his own whose objective was to make rocket manufacture and operation independent of the special skills and experience presumably possessed by the craftsmen who used to make them and reduced to a purely mechanical process. He quickly stopped giving credit not

only to the Indian roots of the rockets he was making but also to the contribution that the tacit knowledge of workers as well as operators in Britain (e.g., from the Navy), on the ground that he was making both fireworks and rockets more “philosophically.” He wrote extensively on the principles of both manufacture and operation and on tactics. As he was implicitly claiming to be the (sole) inventor of rockets and expected that as inventor he should control everything, his project became highly controversial in Britain. In one series of trials which he organized in 1805 as an attack on Boulogne, the test program was a dramatic failure. On the other hand a program organized differently by Capt. Owen of the British Navy in 1806, using the experience and tacit knowledge of Naval officers and men, turned out to be successful and was so acknowledged by Congreve himself. After a detailed account of these programs, Warrett concludes that Congreve “minimised the contribution of both Indian rocketeers and British Naval officers, in a process of orientalizing [in the sense of Said, 1979] and forcing discipline in action,” an attitude that was characteristic of an age when British power spread rapidly across India and elsewhere in the world.

The success in 1806 was followed in 1807 by a barrage of some 25,000 rockets on Copenhagen, which was also very effective. During the next decade the use of such rockets became routine in British naval operations, which included engagements at Aix, Callao (1809), Cadiz (1810), and Leipzig (1813). Congreve rockets were also used in several engagements during the Anglo-American “War of 1812” (see vBO), sometimes with little and on other occasions with great effect. The rockets were still rather unreliable and inaccurate, but had greater range than cannon and could be fired from rowboats. In the battle of Bladensburgh in 1814, rockets played a key role in a British victory, which was followed by a march into Washington and the burning of White House and the Capitol, among other public buildings. On the night of 13–14 September, Fort McHenry was bombarded from Baltimore harbor; the attack was spectacular and (although unsuccessful) inspired Francis Scott Key,

a young American lawyer who was watching it, to refer to “the rockets’ red glare” in a patriotic song he wrote – a song that later became the US national anthem.

The main advantage of these rockets was that their range exceeded that of the movable artillery of that time, and the absence of recoil eliminated the heavy “barrel” required to direct other projectiles. So a rocket barrage could be discharged rapidly from collapsible wooden frames (these would have been no surprise to Tipu’s rocketmen). Congreve thought, rather appropriately, that rockets were “the soul of artillery without the body” (L). But apart from the use of Newton’s laws and some good “systems” thinking, there were few striking conceptual advances; however, manufacture and operational procedures exploited advantages of scale and precision that the industrial revolution in Britain was making feasible. Here perhaps, and in his extensive publications, lay the major contributions of Congreve.

As the “Congreve” rocket virtually became a household word, he succeeded to his father’s position at Woolwich and the baronetcy and was elected to the Royal Society and Parliament. Not all of this was appreciated by his many detractors, who pointed out (correctly) that he never acknowledged how he started with imitations of Indian rockets nor how the tacit knowledge of his own countrymen had made a big difference to his success.

Other countries quickly followed the footsteps of Congreve and the British. Some, like Denmark, Egypt, France, Italy, the Netherlands, Poland, Prussia, Sardinia, Spain, and Sweden, attached rocket batteries to their artillery. Others, including Austria, England, Greece, and Russia, had rocket corps as independent units. The USA also formed rocket units (L).

Although they continued to be used for some more time, there was a considerable decline in the military use of rockets by midcentury, as artillery gained in range and accuracy and became more effective. However rockets found peace-time application in saving lives from shipwrecks. They began to be proposed seriously in 1898 by the Russian scientist Tsiolkovski for space

exploration, and by Goddard in the USA (beginning in 1915), for scientific investigations of the atmosphere. A few decades later they reappeared as military weapons in World War II when Germany attacked England with the V2. Rocket-powered missiles are now part of the military arsenals of many countries in the world.

Conclusion

I hope enough has been said in this essay to make two points. First, in the eighteenth century there were still certain products, of which the rocket was one, where Indian technology was superior to the British and was so recognized by them. Secondly, following this recognition, the British effort to understand and master the technology already had a sophistication that we have come to associate with research and development in this age: scientific principles were applied, appropriate designs were made, and suitable products were developed, tested, systematically evaluated, and produced on an industrial scale.

To understand how this came to happen, we must recall that this period saw what the historians agree was the first wave of the industrial revolution, which Derry and Williams (1960) date as lasting from 1750 to 1815. Simultaneously there was a marked decline in the technological capabilities of India. In the same period Indian exports declined because of stiff British duties, and imports of textiles from Manchester grew rapidly. Although India had for millennia produced iron of high quality and exported it to Britain as late as the early nineteenth century (Tripathi, 2008), the old Indian industry started to decline, and almost vanished by the 1850s, to pick up again only a few decades later but now with British technology (Pacey, 1983, Narasimha, 2012).

The period in question was one of extraordinary turmoil and ferment – political, social, cultural – and was a turning point in global history, especially in India, Europe, and North America. Britain was fighting military engagements at a variety of places around the globe as it laid the foundations for its empire. Europe saw

the French Revolution (1789) and the rise of Napoleon (1795) – and the American colonies of Britain successfully fought a war of independence (1776).

And the birth of modern rocketry that occurred in the same period of global transition can be traced directly to the 30 years of the Anglo-Mysore wars ending in 1799.

Acknowledgments I am grateful to the Indian National Science Academy for allowing me to make liberal use of the material in my article on ‘Rockets in Mysore and Britain (AD 1750–1850)’ in the Academy’s publication *History of Technology in India*, Vol. II (ed. H. Mukhia), 2012.

Rope and Knots in Ancient Egypt

Willeke Wendrich

From securing a ship, to tying cattle to a post, building shelters and curing headaches, rope and string were a multipurpose commodity in ancient Egypt. The technology to make rope and string is presumably one of the oldest, predating stone working. Due to the perishable materials used for rope, no extant examples have survived in Egypt until the predynastic period. The material used most widely for the production of rope was papyrus (*Cyperus papyrus*) and other sedges of the *Cyperus* family. For large ropes, the entire stem was used, while smaller string was made of the rind of papyrus stems. The production of papyrus sheets for writing required the thick triangular stems to be peeled and sliced. The peelings made a strong raw material from which extremely fine string could be made. Many examples of such string were found in archaeological contexts, for instance in cordage from the Giza Plateau, in the rubbish tips of the building phases of Khufu's pyramid (ca. 2600 B.C.E.). Its popularity continued into the New Kingdom. At the workmen's village of Amarna (ca. 1350 B.C.E.) remains of a papyrus amphora carrying net were excavated (Wendrich, 1989, pp. 182–185).

Cordage was made in a large variety of ways. The fibers were spun or twisted in either S or Z direction (see Fig. 1). Two or three strands were plied to form the string, usually twisted in the opposite direction of the orientation of the strands. Two or three strings might be twisted into a cable. Again the orientation was usually the opposite of the twist direction of the ply.

The production of yarn or fine string followed three steps: (1) spinning and splicing (adding short prespun lengths by twisting the fibers in the same direction as the spin) using a spindle whorl; (2) plying in the opposite direction, and (3) cabling in the same orientation as the spin. This type of string was usually made of flax and had a diameter of approximately 0.5–2 mm for

Rope and Knots in Ancient Egypt, Fig. 1 S and Z orientation of spinning, plying, or cabling

the spun and spliced yarn, 1–3 mm for the plied string, and 2–5 mm for a cable. Flax was typically spun and spliced in S direction, then Z-plied and S-cabled (Kemp & Vogelsang-Eastwood, 2002, pp. 75–76).

Producing string of other materials was often done in one phase. Grass string, for instance, was spun and plied in one movement of the hands, the opposite direction of spin (usually z) and ply (usually S) locking the string immediately and preventing it from unraveling (Wendrich, 1999, pp. 298–300). Materials for which this technique was used were tall hard grasses (*Desmostachya bipinnata* and *Imperata cylindrica*), leaf and leaf sheath fibre of the date palm (*Phoenix*

Rope and Knots in Ancient Egypt, Fig. 2 Representation of rope making, using weights in the tomb of Nefer, Saqqara. To the *right*: detail of the action of the man seated in the *middle*

dactylifera), leaf of the doam palm (*Hyphaene thebaica*) and probably also papyrus peel. The result of this hand-rolling technique was a string consisting of two yarns, usually ‘spun’ in Z-direction and plied in S-direction (sZ_2 string). A third plying strand (sZ_3 string) was added separately, by doubling the end of one of fiber bundles and working back along the string. For ropes, the entire length of string was folded double and twisted into a cable ($sZ_2[S]_2$ rope).

Papyrus rope, however, was usually not cabled. The enormous ropes used in shipping consisted of multiple strands of complete papyrus culms [stems] twisted together. Such giant plied ropes were built of up to 15 thick strands of papyrus culms, each with a diameter of approximately 30 mm, resulting in a thick rope of 160 mm in diameter. We have few depictions of rope making, for instance in the tomb of Nefer at Saqqara (Fig. 2), dating to the Fifth Kingdom, ca. 2465–2323 B.C.E.. This seems to be a more industrial approach than the hand-rolling method, which could typically be done by anybody at anytime, whenever a piece of string was needed. The use of swinging weights to make long lengths of rope was most probably needed to twist complete papyrus stems. Presumably the stems were first dried, then soaked (to render them pliable again), twisted into rope and left to dry, so that the twist would settle into a strong plied rope. Toward the Greco-Roman period, grass, papyrus, and doam palm leaf string became less ubiquitous and the material that was used most often was the leaf sheath fiber of the date palm. This hard

brown fiber did not need much preparation. Soaking in water for half a day would soften the fibrous sheets enough to enable them to be worked into small bundles or tufts, which were then used to make a very hard red-brown string or rope. This material was also worked in the hand-rolling method.

Knots and knotting are part of understanding the use of rope. In all periods of ancient Egyptian history, from at least the predynastic period onward, standard knots such as the overhand knot, the reef knot (also known as square knot), and the netting knot were known and widely used. Studying everyday objects from refuse dumps, clarifies that then, as now, certain people were better versed in the art of knotting than others. The occurrence of a considerable percentage of ‘granny knots,’ faulty reef knots, testifies to that effect (Wendrich, 1999).

Depictions of knots and knotting on Egyptian monuments had a very specific meaning. The hieroglyph for ‘protection’ (ancient Egyptian *shen*) represented a rope ring, which surrounded what needed to be protected. The *cartouche*, (French for ‘bullet’) was the protective oval inscribed around the name of the Pharaoh. It represented an elongated rope oval tied at the base.

Knotting had a particularly important protective function in Ancient Egypt. The *tit* amulet, also known as the “Isis knot” represented a looped knot with four ends hanging down. The *tit*, often made of the red semiprecious stone jasper, is thought to be either the girdle of the

goddess Isis, or a tampon, with the function of protecting pregnant women from a miscarriage (Wendrich, 2006). A more symbolic interpretation should be given to the quite common depiction of two nameless Nile gods, or the gods Horus and Seth, knotting the lotus and the papyrus (or the lily), symbols for Upper and Lower Egypt respectively, around a trachea with lungs. This was the hieroglyph for the verb *semaa* and the knotting of a reef knot around this hieroglyphic sign symbolizes the unification of the Nile Valley and the Delta, the two lands that together formed Egypt. In ancient religious texts, such as the Pyramid Texts, the Coffin Texts, and the Book of the Dead, several references were made to knotting. In all cases this seemed to be a protective action, in keeping with the important protective function of knots in medical and magical texts. This forms a stark contrast with terms used for ‘binding,’ or ‘fettering,’ which were used in funerary contexts to describe serious dangers to the deceased. The mummy wrappings were literally considered fetters that prevented the dead from functioning in the afterlife. The action of knotting, however, was related to encircling, the protective embrace, and the guarantee of the integrity of body and *ba*

(The *ba*, a concept often translated as ‘soul,’ is an integral part of a person. The *ba* is depicted as a bird with a human head and is the free-ranging part of a human being. When a person dies, the body is entombed, but the *ba* can exit the tomb, to return each night to the body).

Ahmad Dallal

şadr al-Sharīʿah al-Thaṇī, ʿUbayd Allāh ibn Masʿūd (fl. Bukhārā, d. 747 AH/AD 1347), was a scholar and astronomer of the fourteenth century.

He belonged to a family of famous religious scholars; his great-great-grandfather, şadr al-Sharīʿah al-Awwal, was referred to as the second Abū ḥanīfa in recognition of his rank among the legal scholars of his time. şadr al-Sharīʿah, moreover, was himself a traditional religious scholar: he wrote on the subjects of *ḥanaḫī* positive law, principles of jurisprudence, Arabic grammar, rhetoric, theology, legal stipulations and contracts, and *ḥadīth* (the spoken Traditions attributed to the prophet Muḥammed). In addition, he wrote a three-volume encyclopedic treatise, *Taʿdīl al-ʿUlūm* (The Adjustment of Sciences). The first of the three books is on logic, and the second is on theology (*kalām*). The questions discussed in these two books were not unfamiliar to theologians of the time, and it seems quite probable that a jurist would be informed in such areas of research. What is uncommon, however, is şadr al-Sharīʿah's competence in astronomy, which he demonstrates in the third book of the above work.

This last section entitled *Kitāb Taʿdīl Hayʿat al-Aflāk* (The Adjustment of the Configuration of the Celestial Spheres) was finished in the year 747 AH (AD 1347) shortly before the death of its author. The motive for writing it, as expressed by the author in the beginning of the book, was to resolve the problems of the longitudinal motion of the moon and the other planets, as well as the latitude motion. The resulting work is indeed a revision of the astronomical tradition from within its own existing framework. In this şadr al-Sharīʿah was obviously driven by the momentum of the revisionist tradition of the thirteenth-century Maragha school, which aimed at reforming Ptolemaic astronomy.

şadr al-Sharīʿah was especially influenced by two sources: the *Tadhkira* of Naşīr al-Dīn al-ṭūsī (d. AD 1274) and the *Tuhfa* of Quṭb al-Dīn ► [al-Shīrāzī](#) (d. AD 1311). şadr al-Sharīʿah proposed to review critically the planetary models of his two predecessors, and in the course of this revision he proposed his own alternative configurations. The models which he purported to examine and replace were for (1) the longitudinal motion of the moon, (2) the longitudinal motion of the superior planets, (3) the longitudinal motion of Mercury, and (4) the motions in latitude. The mathematical mechanisms utilized by şadr al-Sharīʿah to solve the problems of these models were not new, but his ingenuity lay in bringing some of these different mechanisms together.

In three of the above cases he succeeded in producing new models, and in at least two of these the resulting configurations seemed to resolve the theoretical problems of earlier models, while predicting the planetary positions in accordance with the Ptolemaic observations.

Salt

S. A. M. Adshead

Salt, its production, distribution and consumption, was an important element in the economies of all ancient societies and played a significant role in their societies, politics, and culture. This article falls into two parts. First, the principal methods of producing salt before 1800 will be analyzed. Second, the particular methods in use in the four primary civilizations of Western Eurasia (excluding Europe itself), East Asia, sub-Saharan Africa and pre-Columbian America will be outlined, together with their characteristic means of distribution and levels of consumption.

Salt exists in nature in two forms. First, there is actual salt. This takes the form of rock deposits from evaporated seas which can be quarried or mined, spontaneous evaporation at the edge of the sea or saline lakes, and incrustation on the surface of saline soil, both of which may be collected. Second, there is potential salt. This takes the form principally of brine from the sea, lakes, springs or wells, but also of saline earth and the plants growing in it. From potential salt, actual salt can be made by a variety of techniques. In most non-Western cultures these techniques were more important as a source of salt than quarries, mines or collection. Evaporation of brine, whether from the sea, lakes, springs or wells, or artificially prepared from saline rock, earth or plants, accounted for 90 % of all salt consumed before 1800. Brine could be made to yield salt in two ways. It could be boiled over an artificial fire and fueled in various ways: what the Chinese called *chien*. Or it could be evaporated naturally by the power of the sun and wind: what the Chinese called *shai*. Artificial boiling and natural evaporation produced different kinds of salt. Quicker, *chien* produced a small-crystal salt, or, if prolonged, cake salt. Slower, *shai* produced a large-crystal salt. Each method had subvarieties whose differences varied the cost, color,

consistency, purity, and cleanliness of the salt produced.

Subvarieties of artificial boiling may be classified according to the fuel used. Wood was commonest, but reeds, natural gas, coal, and oil shale were also used. Fuel was the chief item of cost and its availability the principal constraint. The amount required depended on the salinity of the brine. To reduce it, brine salinity was frequently intensified either by preliminary exposure to sun and wind or by filtration through saline sand, earth or ash. Since artificial boiling was everywhere an older method than natural evaporation, it may have been this preliminary exposure which provided the idea of using sun and wind to effect the whole process.

Subvarieties of natural evaporation may be classified according to the number and function of the basins used. First, there was single basin evaporation. Here, brine was run into a single basin, or battery of basins, and allowed to evaporate completely. Salt made in this way, however, was gritty, deliquescent, and possibly injurious to health, because the sodium chloride would be contaminated by the calcium and magnesium compounds contained in most brines and especially in sea water. Next, there was successive basin evaporation. Here, brine was run through a series of basins for catchment, condensation, and crystallization. In this way, sodium chloride could be separated from the calcium and magnesium compounds through the different sedimentation rates of these chemicals. Thus the calcium compounds settled in the condensers, while salt was removed from the crystallizers before it could be contaminated by the magnesium compounds in the mother liquor which was then drawn off. By this triple process, a much purer sodium chloride was obtained. The process could be tuned to give different degrees of cleanliness and size of crystal by varying the frequency of harvest and the ratio of condensers to crystallizers. The more frequent the harvest, the more likely the adherence of the floor of the crystallizer to the salt, so the dirtier the product. The higher the ratio of condensers to crystallizers, the longer the process, so the bigger the crystals. The choice of frequency and ratio depended on cost,

especially of land, convenience to the producer, climate, and consumer preference as to the kind of salt. Salt was a sophisticated industry.

Salt has been sought since the first agriculturalists found a vegetable diet bland and insipid compared to meat and fish. It was sought too for its supposed medicinal effects on the internal parasites with which early agriculturalists were endemically affected. Finally, as the "general of foods," it was sought to create flavor, cuisine, and social distance. Salt was an adjunct of civilization. Although the body does require a minimum intake, the quantity is small and satisfied by normal diet, so that salt deficiency is rare in humans.

Most human consumption is in excess of physiological need. Culture, not nature, called for salt. It traveled by whatever form of transport was cheapest for bulk goods, which in premodernity meant by water, where available, rather than by land.

In the Ancient Near East and in its successor the Central Islamic lands, natural salt in the form of rock, spontaneous evaporation and incrustation was widely distributed. Salt never became big business and consumption was high. When Muslims moved beyond their homeland, however, they experienced a shortage of salt. The expansion of Islam to the Mediterranean, North Africa, India, and Indonesia was therefore accompanied by the introduction of new techniques of salt production. In particular, Islam diffused the Chinese technique, invented around AD 500, of successive basin solar cum wind evaporation. That the technique was diffused rather than independently invented in a number of places is indicated by the presence everywhere initially of the original Chinese condensers to crystallizers ratio, itself functionally unnecessary and in some circumstances dysfunctional.

In China itself, before AD 500, salt had been acquired either, in the northwest, by the collection of natural deposit, or, in the southeast, by boiling of marine brine (*chien*). Initially *shai* was regarded as inferior to *chien*. Indeed, in the Mongol period it was temporarily abandoned in its original site. In the long run, however, its absence of fuel costs, plus a number of technical improvements, gave it complete victory over *chien*, save

in Szechwan which enjoyed the advantage of natural gas and more saline brine. In India too, though the mines of the Salt Range continued to operate, successive basin solar evaporation became the chief form of production: principally at the Sambhar Lake and on the west coast, but subsidiarily, with technical modifications, in Tamil Nadu. Bengal long remained a center of *chien*, till its industry was overwhelmed by imports from Britain and the Red Sea, the latter being a *shai* center.

In pre-Columbian America and in sub-Saharan Africa, production remained limited and consumption low until the coming of the Europeans to the first and of Islam to the second. Some Matto Grosso Indians neither produced nor consumed salt (the same is true of the Maori in New Zealand). Elsewhere in America, supply was by collection, boiling, or single basin evaporation, though one archaeological site has raised the possibility of an independent Maya invention of the successive basin technique. In Africa, supply was similar, though the Saharan quarries and mines may have been developed before the coming of Islam. The greatest consumers of salt were the Islamic world and China. Despite the development of marine based salines at its extremities, Islam supplied itself mainly by land, using camels for transportation. China supplied itself mainly by water, by junk. There, because sources of supply, chiefly on the coast, were relatively few, salt did become big business. Indeed, until it was supplanted in the eighteenth century by textiles, it was the chief component of the premodern Chinese economy.

Salt in Bengal

Indrajit Ray

Department of Commerce, University of North Bengal (on lien), Darjeeling, West Bengal, India
Cooch Behar Panchanan Barma University,
Cooch Behar, West Bengal, India

Long before the advent of British rule in Bengal, the salt industry was developed in its coastal belt stretching over about 700 mile. The prominent places of production were Tamlook and Hijli in the Midnapore district, the Sunderbans in the 24 Parganas, and Noakhali and Chittagong in the present-day Bangladesh. During the Mughal period, the salt merchants enjoyed the highest status in the trading society, and its highest bidder received the title of *fakir-ul-Tejar*. The technology of the industry was, however, based on traditional knowledge and practices, requiring locally manufactured implements. Since the caste-based division of work largely prevailed in the society, it percolated down the generations. Though, under the governance of the English East India Company, several reforms were tried on the industry's organizational aspects, its traditional technology was left unaltered. In 1836, the industry turned over around 246,000 t, giving employment to about 16,500 salt workers (*molunghees*) and 133,000 subordinate workers. The province was largely fed out of it and also its surrounding neighborhood.

The technology required saline water and saline earth as raw materials. They were mixed together and filtered suitably to obtain brine, which was afterward boiled and dried up to get the end product. Four technical processes were thus involved in this manufacturing: processing of raw materials, filtration, boiling, and drying. The salt manufacturing unit in Bengal was, however, called *khāllāri* (saltworks), which a *molunghee* operated with the help of his subordinate workers. It was set up on a salt bed (locally called *char*) over one-half to three bighas of land (1 bigha = 1,600 square yards), where he set up three salt fields (*chatturs*) for the collection of

saline earth, reservoirs (*joorees*) for holding saline water, a filter (*maidah*), a boiling house (*bhunri ghar*), and a drying house (*khuttee*). Locations of these centers were decided upon keeping in view the order of various technical processes in production.

Processing of Raw Materials

The initial task of a *molunghee* was to identify the land for saline earth and to divide it into three small rectangular fields (*chatturs*) of equal sizes. He then carefully uprooted all the weeds and shrubs from those fields and dug out their surface soil by about five inches, allowing the saline water to fill up the holes. The soil thus removed was used for the embankment of the *chatturs*. During the months of July and August, the fields were frequently plowed so that the saline component of water was impregnated in the soil. When the soils were thus sufficiently enriched with salinity, they were leveled by a lump crusher (*moi*) and left to the exposure of the sun for 5–6 days. It caused the saline component of the soils to come up in the surface in the form of small (as well as soft) blisters. When the *chatturs* were thus ripened, the process of *chāppākurna* began. It involved 7–8 persons standing side by side and moving their legs vertically and horizontally so that every saline blister in the fields was crushed. The fields were then again left to the sunrays for 7–8 days so that all the moisture of the ground was evaporated and the saline earth on the surface became dust. The dust saline earth was scraped by a *khoorpā* (made of one piece of iron and two handles) and collected in small heaps in the field. This was a crucial raw material for the industry.

For the other raw materials, viz., the saline water, a reservoir (*jooree*) was dug to a depth of 4–5 cubits on 2–4 *kathas* of land (1 *katha* = 80 square yards). It was connected through a small drain with a river or a canal so that it received the saltwater at high spring tides. Old *joorees* and drains were filled with rainwater during the rainy season. But *molunghees* cleared it by the end of September so that only the saline water was stored there from the first spring tide in

October or in early November. From each returning tide, however, saline water was stored for about 20 days of production.

Filtration Process

In Bengal's traditional technology, brine was prepared through the filtration process. The filter (*maidah*) was a pyramid-shaped, mud-built structure, $4\frac{1}{2}$ cubits in height and $12\frac{1}{2}$ cubits in breadth at base tapering to $7\frac{1}{2}$ cubits at the top (Fig. 1). A basin was fitted at its summit. It was roughly $1\frac{1}{2}$ cubit in depth and 5 cubits in diameter, and its bottom was made of clay, ashes, and sand with a hole at its center. An earthen pot (*koonree*), which was also centrally pierced at its bottom, was fitted there with their holes perfectly in alignment so that a hollow bamboo could be fitted through those holes at its one end and an earthen pot (*nād*) at the other. This hollow bamboo acted as a pipe for the movement of filtered saline water from the basin to the *nād*. A filter was, however, placed on the top of the *koonree*. It was made of a light bamboo frame containing a layer of straw and a layer of saline earth. The earth was repeatedly stamped with the feet to make it hard. The *nād* could, however, contain 30–32 *gharahs* (earthen vessels) of saltwater (each *gharah* contained about $3\frac{1}{2}$ gallons of water).

The process began with two *coolies* (porters) carrying salt earths from the *chattur* and throwing them into the basin. They used a carrier called *jhoolah* (a frame of two bamboos with a rope network), which could carry one-half to two maunds at a time (1 maund = 37 kg). When the basin was filled up to the brim, 3–4 persons began to knead the earth with their feet while the saline water was gently poured into it from the *jooree*. The process continued till about 80 *gharahs* of saline water were absorbed. The water was filtered down to the *nād* through the hollow bamboo pipe. By way of such a filtration process, 80 *gharahs* of saline water yielded 32 *gharahs* of strong brine.

Porters then carried the brine from the *maidah* to the *thannah nād* (a receiving pot) that could contain 30–40 *gharahs* of brine. It was kept

Salt in Bengal,

Fig. 1 Filter for salt manufacturing (maidah)
(Source: Hamilton, H.O. "Notes on the manufacture of salt in the Tamlook agency" p.15)

outside the boiling house. The brine was left to settle there for about 24 h so that impurities were precipitated out at the bottom.

Boiling Process

The boiling house (*bhunri ghar*) was built to the north and south near the *chattur* (Figs. 2 and 3). For an area of 25–26 cubits $\times$ 7–9 cubits, it took about 1–1½ *katha* of land, encompassing a store-house for fuel (*jullan thannah*) as well. Its northern wall was highly elongated – about 6 cubits in height as against 3–3½ cubits in height for the southern wall – for the accommodation of the furnace. The southern space was meant for the lodging of workers. An earthen furnace (*choolah*) was, however, built in its northern space, rising about 2½–3 cubits from the ground, with a boiler (*jhānt*) on its center. Since the boiler was semicircular, about 5 cubits in diameter, it was called *jhānt chakkra*. About 200–225 small earthen pots of conical shape (*koonrees*) were arranged on the *chakkra* in a pyramidal shape and cemented together with clay. Each pot could contain 1½ *ser* of brine (1 *ser* = 0.93310kg.).

Before boiling was started, the *molunghee* made every arrangement to ensure that there

was no interruption in the process. A cooly (porter) was posted on the southern side of the *choolah* with a bamboo-made, two-pronged fork (*jalthellee*) to continuously supply fuel. All the *koonrees* were filled with brine, and the *molunghee* stood near the *koonrees* with a ladle (made of a coconut fixed to a piece of bamboo) to pour brine into them whenever it was partly evaporated. Then the fire was lit, and the *pokhtan* (boiling) commenced. The *molunghee* went on pouring brine into the *koonrees* until a ratio of 3:1 was attained between salt and water. It, however, took 4–5 h for the formation of salt granules. Four to six maunds of salt were thus obtained at a time.

The salt granules were then collected in two baskets (*joorahs*) and kept by the side of the *choolah*. This was, indeed, the initial process of drying. Subsequently, however, those *joorahs* were dispatched to the drying house for further drying treatments.

Drying Process

The drying house (*khuttee*) was a square enclosure with one storeroom (*golah*) at each side (Fig. 4). Its floor was specially built up by a

Salt in Bengal,**Fig. 2** Interior of a boiling house (*bhunri ghar*)

(Source: Hamilton, H.O. "Notes on the manufacture of salt in the Tamlook agency" p.18)

**Salt in Bengal,****Fig. 3** Exterior of a boiling house (*bhunri ghar*)

(Source: Hamilton, H.O. "Notes on the manufacture of salt in the Tamlook agency" p.17)

mixture of ashes and earth, making its surface very smooth and hard. Its center was slightly elevated with a slope toward an inside drain, which carried out bittern (*gewa-rus*), i.e., the moisture that exuded from the salt. The *golahs*

were usually 21 cubits in length, 7 cubits in breadth, and 4½ cubits in height.

In addition to the initial process of drying, four further treatments followed: (a) The *joorahs*, dispatched from the boiling house, were brought

Salt in Bengal,

Fig. 4 Drying house (*khuttee*) (Source: Hamilton, H.O. "Notes on the manufacture of salt in the Tamlook agency" p.20)

Salt in Bengal, Fig. 5 *Joorahs* on a bamboo frame (Source: Hamilton, H.O. "Notes on the manufacture of salt in the Tamlook agency" p.21)

inside the *khuttee* and kept on a bamboo-made frame, about one cubit in height, for 12–24 h (Fig. 5). Through this process, the aqueous contents of salts dropped down on the ground so that they were dried up to some extent. (b) After this stage, the salts were stamped (*adulled*) with wooden stamps to crush the lumps of salts into grains, and brought inside the *golah*; they were kept on its floor for 1–7 days so that the earth further absorbed their aqueous contents. Thereafter, they were collected in a heap, which was locally called *maharas kundy*. (c) The *maharas kundy* salts were then brought out of the *khuttee*

and kept on the elevated floor of the *golah* for some days. A few inches of its lower stratum got slightly discolored as the bittern oozed out, but the superincumbent mass of the heap became pure white, when all the moisture was tolerably drained off. And (d) in the final round of treatment, which local people called *baharkandy*, the salts were brought outside the *golah* and heaped in an open space opposite to it. They were then *adulled* all over and thatched with straws or grasses with a view to preventing the high winds from blowing them away (Fig. 6). A layer of clay or mud was placed at the base of the heap to absorb the

Salt in Bengal,

Fig. 6 The *baharkandy*
(Source: Hamilton, H.O.
'Notes on the manufacture
of salt in the Tamlook
agency', p.22)

moisture of the salts. They were left in that state for about a fortnight when the clay layer was replaced 3–4 times.

The salts thus manufactured were called *punga* salts in the contemporary market nomenclature. There was another variety of salt, called the *kurkutch* salt, which was manufactured by solar evaporation. But it was of very little significance in Bengal. In this process, the brine was obtained in the same way as followed for the *punga* salt. The difference lay in that the *kurkutch* brine was poured into salt pans by a depth of 1½–2 in. and was left to the exposure of the sun for 2–4 days. By way of evaporation, the *kurkutch* was granulated.

The manufacturing process for the *punga* salt, as described above, was typically followed in most places in Bengal. In Chittagong, however, slight deviations took place. The salt lands were selected there on the coast of the Bay of Bengal, or at its proximity. Salinity in the earth was so high in those lands that they did not need to be submerged for the impregnation of salinity. During the spring tides in October and November, highly saline earth could be obtained from the surface soil. The boiling process was also slightly different in those *khāllāries*. Two alternative methods of boiling were followed there, and they were called *jat* salt and *telinea* salt. In the former case, the boiling arrangement was similar to what we have described above, but the boiling house was fenced with bamboo and grass without any roof. In the case of *telinea* salt, however, the furnace was different. It was not raised above the

ground, but sunk in the earth. A cone (*kanda*) was constructed over it to contain about 180 pots (*telins*). There were also differences between Chittagong *khāllāries* and others in respect to the capacities of filters, reservoirs, and drying arrangements.

Contemporary market surveys reveal that people in Bengal preferred the *punga* salt over the *kurkutch* salt, or even the salt imported from Liverpool. But there was a great debate throughout the nineteenth century on the hygienic aspects of its production, and this culminated in statutory prohibitions on the technology in 1898. The allegation against the indigenous technology was that it used “the dirty and slimy brine of pestiferous marshes.” But a contemporary government official remarked “The boiling, indeed, being effected in small pots supplied with clear brine, and skimmed from time to time as impurities rise to the surface, struck me, when I saw the process, as peculiarly favourable to purity, though laborious, and expensive in the use of fuel, and I am not aware that the notion has been contradicted by an analysis.” (Ray, 2001 p. 190).

Salt in China

Hans Ulrich Vogel

In premodern China, hundreds of terms for different kinds of salt existed which were distinguished according to place of origin, type of deposit, method of production, shape, physical appearance and properties, taste, color, translucence, use, and function within the salt monopoly system. An important and authoritative scientific explanation for the existence of various salt deposits was provided by the *Shujing*. There, in the chapter “Hong fan,” saltiness (*xian*) is related to the phase of Water, which by soaking and descending becomes salty. Another important explanation referred to cosmogonical thinking, stating that the clear and light (i.e., underground currents of sweet water and water of rivers and lakes) are to be found above, while the heavy and turbid (i.e., underground brine and sea water) below.

The economically and fiscally most important types of salt were, in descending order, sea salt (*haiyan*), lake salt (*chiyan*), well salt (*jingyan*), earth salt (*jianyan* or *tuyan*), and rock salt (*yayan*). In the late imperial period, sea salt accounted for more than 80 % of the empire-wide production. The percentages for lake salt and well salt were about 12 and 6 %, respectively. The shares of earth and rock salt are quantitatively negligible.

The Chinese salt production sector reflects typical features of the history of production techniques in China. The far greatest amounts of salt, that is sea, lake, earth, and rock salt, were produced with the help of rather simple and old-established production techniques, which in many cases required a high input of human labor. Manpower also played an important role in well salt production, but, because of the use of deep-drilling methods and exploitation of natural gas resources, this sector contained a revolutionary technological potential. Finally, we can observe that, sometimes, sophisticated production techniques were abandoned, like the method of basin solar evaporation at the salt lake of Xiezhou in Hedong (Shanxi) during the thirteenth to the sixteenth centuries.

Several partly overlapping stages of development may be observed in the production of sea salt. Early sources mention that salt was produced by boiling seawater. It is, however, far from clear whether this statement refers to the rather uneconomic process of boiling seawater directly down or whether prior to boiling a concentrated brine had been prepared. Probably both methods coexisted.

The first written account of the production of concentrated brine comes from the late ninth century. A hollow was dug, covered with wood and ► bamboo twigs. Sands enriched in salt were heaped up over the hollow and were then leached out by the invading flood. The concentrated brine dripped into the hollow and was tested with grains of cooked rice which floated or descended according to the degree of salinity. Finally, the brine was boiled to salt in iron pans, or pans made out of woven bamboo strips and coated with a layer of clamshell lime. This became the basic method of sea salt production in China. Improvements were added in later ages. For instance, besides sand, ashes were used which were spread out on specially prepared fields, artificially sprinkled from time to time, and exposed to the sun, thus raising their content of salt particles. In this way, the amount of brine and its salinity could be increased. The sophisticated and labor-intensive process of later ages is fully described and illustrated in the *Aobo tu* of 1334 (see Fig. 1).

Salt in China, Fig. 1 Sea salt production from the *Aobo tu* of 1334, with the title “Carrying the ashes and pouring them into the leaching basin”

The production of sea salt by solar evaporation (*shai yan*) began probably in the late Song period. The term *shai yan* is, however, ambiguous. It may either denote the production of salt in successive solar evaporation basins, making use of the fact that common salt would crystallize *after* the precipitation in the condensers of the calcium salts contained in the brine and *before* the precipitation of the magnesium compounds. Or it may be connected with the traditional leaching process, in which the last step in the production process, the boiling of enriched brine, was simply replaced by solar evaporation. The latter technique may be considered a transitional step in the slow shift from the original method of boiling brine to the production of salt in successive solar evaporation basins. This transitional method had probably already begun in the late Song period. A special form developed in parts of eastern Zhejiang where from the late eighteenth century onward the enriched brine was exposed to the sun in portable wooden trays.

While Adshead (1990, 1992) thinks that successive basin solar evaporation of sea salt first appeared in Changlu (Hebei) in 1522 at the latest, and then spread to Huaibei (1550), Shandong (1570), Fujian (1575) and other places, Liu (1988) is of the opinion that it was not adopted at the sea coast before the middle or late sixteenth century. Moreover, there is clear evidence that Fujian was prior to Changlu which took over the

method of successive basins from Fujian perhaps in the middle or late sixteenth century (Bai, 1988; Lin, 1992). From the seventeenth century onward the method of solar evaporation in successive basins gradually replaced the traditional methods of preparing enriched brine for the final crystallization either with the help of fire or solar heat. Generally speaking, either method of solar evaporation resulted in economies of fuel and manpower.

The use of solar evaporation basin methods, however, did not originate at the sea coast, but at the salt lake of Xiezhou in southern Shanxi. In the beginning of Chinese culture, this lake must have been an important and contested source of salt supply. First, salters extracted naturally and spontaneously produced salt, a process which had always been considered an auspicious and divine phenomenon. In the late fifth or early sixth century at the latest artificial solar evaporation basins emerged. For both methods of harvesting (see Fig. 2), the warm southern wind of the summer months was a decisive factor in bringing about crystallization. Salt production in basins was conceived basically as a kind of agricultural process which is suggested by the use of terms like “fields,” “parterres,” “ditches,” “raised paths,” and “sowing salt.” From the late thirteenth to the late sixteenth century, however, solar evaporation basins were given up, and probably only naturally and spontaneously produced salt was

Salt in China, Fig. 2 The two methods of harvesting salt at the salt lake of Xiezhou, as shown in the *Zhenghe* pharmacopoeia of 1249

extracted. Political reasons were partly responsible for this, because the method of solar evaporation basins was closely associated with the saline's corvée [a form of unpaid labor required by a lord] system. Solar evaporation basins were reintroduced in the late sixteenth century. A perennial problem was the protection of the salt lake's brine reservoir from intruding fresh water floods caused by inundating rivers. Dikes and spillover areas were constructed for this purpose. One of these inundations silted up the lake's brine reservoir in 1757, so that thereafter wells and pits were constructed for getting brine.

Whether single basin or successive basin solar evaporation was carried out at Xiezhou is debatable. Successive basin solar evaporation was

explicitly described for the first time in the early eighteenth century. Educated guesses about the actual date of invention or adoption of successive basin solar evaporation at Lake Xie, however, vary greatly. It is said to have been either the fifth or sixth century (Adshead, 1992), the eleventh century (Chai, 1993) or the late sixteenth century (Vogel, Needham et al., forthcoming).

The production of well salt in Sichuan province can be divided roughly into two periods. From the third century BCE to the eleventh century AD shaft wells were dug for exploiting the underground brine deposits. Recent research has shown that deep drilling was invented in the 1040s, thus inaugurating the era of deep drilled wells from the middle of the eleventh century up to the twentieth century. Salt produced by

Salt in China, Fig. 3 A Sichuan salt well, as depicted in the Sichuan salt gazetteer of 1882

privately run deep drilled wells was cheaper and of better quality than that offered by the state managed shaft wells. The new type of well was drilled with a heavy iron bit which was fastened to a cable made out of ► [bamboo](#) strips notched together. The cable was attached to the drilling frame's lever beam. By jumping up and down the lever beam the drill was lifted and dropped, thus crushing the rock down in the well and creating a hole with a diameter of only about 13 cm. The upper part of the finished well was tubed with large bamboo stalks. From the late sixteenth century onward it was also provided with a foundation of stone rings, and large tubes made out of wood were used. Slurry and brine were lifted with a bamboo tube which was equipped with a leather valve at its lower end. When entering the brine, the valve opened inward, and it closed under the pressure of the brine when the tube was lifted. A great number of utensils were invented to remove obstructions that occurred during the process of drilling and brine hoisting. Deep drilling,

hoisting, and repair operations developed in the course of time. This development was characterized by the use of heavier drill bits, more solid drilling frames, higher hoisting rigs, and larger hoisting tubes and hoisting drums, driven by up to four buffaloes. While in the mid-eleventh century a depth of about 200 m may have been sometimes reached, wells of the mid-eighteenth century may have been more than 500 m deep. And in 1835, the Xinghai well of Furong (*Ziliu jing*) measured more than 1,000 m. The nineteenth-century Furong wells (see Fig. 3) were much more successful than their predecessors in the tapping of subterranean brine and natural gas deposits.

Earth salt was produced in northern Shanxi and eastern Hebei in a way similar to producing sea salt, that is by leaching earth containing salt particles and by boiling down the resulting brine. The exploitation of rock salt was reported from Gansu and Shaanxi, where a kind of red-colored salt was collected in rocky caves.

Salt in India

S. D. Gomkale

As India is one of the oldest civilizations, it is no wonder that salt was produced in ancient India and that one finds its mention in ancient scriptures. The salt industry flourished as a cottage industry for centuries. The word for salt is

Lāvaṇa in Sanskrit. A passage from *Arthaśāstra*, a book dealing with the history of the Mauryan period (300 B.C.E.), says that salt manufacture was even at that distant date supervised by a state official named Lavanadhyaksa and the business was carried out under a system of license granted on the payment of fixed fees or part of the output. This tradition, handed down from Hindu kings of old, is even now followed with variations by the Government of India through its Salt Department. The history of many countries shows connections with salt; in India salt was used by Mahatma Gandhi as a tool to win independence, when he completed his famous 400-km march to the sea at Dandi on 6 April 1930. The development of the Indian salt industry will now be briefly examined in two periods, pre- and post-independence.

Salt was prepared in ancient times and until British rule from sources like seawater, subsoil and lake saline water, rock salt deposits, and water extracts of saline soils (particularly in Uttar Pradesh) mainly by solar evaporation. If required, artificial evaporation was resorted to. The salt was produced in the coastal regions of Bengal, Bombay, Madras and the Rann of Kutch and in the inland regions of Rajasthan, Uttar Pradesh, and Central India from saline brines of lakes and as rock salt in Punjab. The salt industry provided a source of revenue to the rulers in the respective regions, and it received protection and encouragement from them. However, the industry faced a sort of setback and discouragement from the British rulers who not only raised the taxes and levies as early as 1768 but also later started importing salt around 1835–1836 from European countries, Aden, and other places. The salt industry in Bengal province first felt the impact of the British policy which then affected the salt industry not only in other parts of their empire but also in Goa, which was under Portuguese rule. The quantity of salt imported, mainly in Bengal, in the pre-independence period ranged between 0.4 and 0.6 million tons annually.

However, the British rulers reconsidered their drastic policies around 1930–1931, which helped to revive the Indian salt industry, and salt production picked up. Changes and improvements in salt

production methods, particularly from sea water, based on scientific principles were brought about by an Indian chemical engineer, Kapilram Vakil. Before establishing India's first large scale marine salt farm at Mithapur in 1927 with the support of the Maharaja of Baroda, he had earlier (1919–1920) studied in detail the status of the salt industry in the eastern states of Bengal and Orissa. Thus production of salt in large salt works established on the basis of scientific knowledge began in India before independence.

After Independence, the majority of rock salt producing areas went to Pakistan. Salt is now mainly produced from sea water, subsoil brines, and inland lake brines. India exports salt; the imports are around 8,000–15,000 tons per year in recent years and it is mostly as rock salt from Pakistan.

Efforts have to be made to improve the quality of salt produced from both sea water and subsoil brines in the field itself, and this is one of the challenges faced by the Indian salt industry. The industry is highly labor intensive and thus has a low output. It is necessary to upgrade the technologies, adopt mechanization, and improve transportation, loading, and port facilities. This is another challenge to be tackled by the Indian salt industry, an ancient industry that must adapt to changing times.

Salt Production in Mesoamerica

Eduardo Williams

Centro de Estudios Arqueológicos (CEArq), El Colegio de Michoacán, Zamora, Michoacán, Mexico

Common salt, or sodium chloride, has always been a strategic resource of primary importance.

In pre-Hispanic Mesoamerica salt was used mainly for human consumption, as the native diet (consisting mainly of plants such as maize, beans, chili peppers, and squash) had little chloride and sodium (Williams, 2003). Chloride is essential for digestion and respiration, and without sodium our organism would be unable to transport nutrients or oxygen or transmit nerve impulses. Throughout the world, once human beings began cultivating crops, they began looking for salt to add to their diet (Kurlansky, 2002, pp. 6–9).

In the preindustrial world, sodium chloride had several important uses apart from its role in the diet, particularly as preservative of animal flesh, as a mordant for fixing textile dyes, as a medium of exchange, and as a principal component in the preparation of soaps and cleansing agents (Parsons, 1994, p. 280).

An ancient technology where salt was very important was textile dyeing. There may have been a direct functional link between saltmakers and cloth dyers in Mesoamerica; saline solutions have been commonly used as mordants by traditional cloth dyers in several parts of the world to fix dyed colors in textiles (Parsons, 2001, p. 241). In fact, salt's important role in the Mesoamerican economy can be indirectly gauged by the huge number of dyed textiles that circulated through commerce and tribute. Among the Aztecs, for example, cotton cloth had many uses. Cloth was used for clothing, bedding, bags, awnings, decorative hangings, battle armor, adornment for statues of the gods, and shrouds for the dead (Smith, 1998, p. 91). Cotton textiles served as items of exchange, as well as currency in the markets; they were exchanged as gifts among the nobility, and formed the dominant item of tribute payment at all levels (Smith, p. 91).

Imperial tribute received by the Aztec state every year included 128,000 mantles or capes, 19,200 garments, and 665 warrior costumes. Most of these items were woven with dyed cotton thread, and the amount of salt used in the dyeing process must have been very high indeed. To this we should add the 4,000 “salt loaves” paid to the Aztecs by several tributary provinces every year (Smith, 1998: Table 7.2).

Salt Production in Mesoamerica, Fig. 1 Map showing salt-producing sites in central-western Mesoamerica (© Eduardo Williams)

Throughout Mesoamerica, salt was one of the most important items of trade and tribute. Access to major natural sources and control of long-distance salt trade was a fundamental factor in the formation of states. Among the Maya, for instance, many ancient trade routes had one or two key resources, whose exchange was the stimulus for the origin and growth of commerce. One of these resources was salt and to a lesser degree cotton, obsidian, and jade (Andrews, 1983, p. 134).

The Tarascans of west Mexico expanded their empire from their homeland in central Michoacán (Fig. 1) toward the Lake Cuitzeo basin in the east, the Sayula Lake in the west, and the Pacific coast of Michoacán and Colima to secure many strategic resources such as salt, obsidian, copper, gold, and silver, which were lacking in the empire's heartland (Pollard, 1993; Williams, 2003).

Mesoamerican salt sources can be broken down into three types: saline inland lakes, highland springs, and coastal estuaries (Kepecs, 2003, p. 126). The methods used to extract salt in pre-Hispanic times consisted of boiling brine,

leaching brine through salt-laden earths, and solar evaporation. These processes often were combined (Kepecs, p. 127). Salt itself is usually not preserved in the archaeological record. The archaeological markers or material remains linked to saltnaking with native techniques consist of (1) pottery vessels (which were used and discarded in great quantities at salt production sites); (2) shallow solar evaporation ponds made of sand and lime; (3) canals for taking the water from the springs to the production sites; and (4) mounds of leached, discarded earth (Williams, 2003).

Salt production and trade played a fundamental role in Mesoamerican culture from the earliest times. By 1200 BCE, Olmec merchants from the Gulf of Mexico penetrated highland and Pacific coastal Guatemala, Oaxaca, and central Mexico in their quest for salt and various other strategic resources such as obsidian, jade, serpentine, iron ores, basalt, cacao, marine shells, animal pelts, and exotic bird feathers. Olmec traders actively engaged in salt extraction and trade along the Gulf coast in the Formative (Diehl, 2004, p. 128). During this same period in Oaxaca

saltmaking was restricted to villages near saline springs. As early as 1300 BCE some salt-making areas were visited briefly, but no houses were built. During the Middle Formative (ca. 900–300 BCE), the production of salt by boiling brackish spring water in pottery jars was a common activity. Saltmaking was probably one of Formative Mesoamerica's most widespread regional specializations (Flannery & Winter, 1976, pp. 39–40).

What follows is a brief discussion of pre-Hispanic saltmaking in several areas of Mesoamerica. This discussion is based on archaeological, ethnohistorical, and ethnographic data (for a detailed discussion, see Williams, 2003).

The Basin of Mexico

Parsons (1994, 2001) studied saltmaking at San Cristóbal Nexquipayac, a small village on the northeastern shore of Lake Texcoco, central Mexico. According to Parsons, saltmaking at Nexquipayac involves six basic sequential steps:

1. Collecting the soils whose salts are to be leached
2. Mixing the soils in the correct manner
3. Filtering the water through the soil mixture in order to leach out the salts and concentrate them in a brine solution. A conical pit excavated in the workshop to a depth of 40–50 cm and 90–100 cm in diameter was used for this
4. Boiling the brine to obtain crystalline salt
5. Drying the crystalline salt and
6. Selling the dried salt (Parsons, 1994: 263, 269, 2001).

The Sayula Basin, Jalisco

The initial process used to extract salts in the Sayula basin must have been the leaching of saline sediments. The leaching process consisted of “washing” and filtering saline earth with fresh water; the result was a salt-laden liquid or brine. This stage of production required various types of installations. The producers built a filter

sustained by a wooden fork, composed of a rectangular base of sticks on which sedge, fodder, and sand were placed. The resulting brine was collected in a circular pan (Valdez, Liot, & Emphoux, 1996, p. 179).

Following the extraction process, it was necessary to reduce the collected brine through natural or induced evaporation to achieve the final product – salt. Although salt production carried out until recently in the Sayula basin relied on solar evaporation, the historical texts always refer to fire reduction in ceramic vessels (Liot, 2000; Valdez et al., 1996, p. 179).

Cuyutlán, Colima

In pre-Hispanic times, the most common salt-making technique in coastal Colima was by boiling the brine. When seawater or water from saline wells was not used, it was necessary first to obtain water with a high saline content, or brine, through several processes of leaching and washing of saline soils; later the resulting brine was boiled to evaporate the water. Both processes, filtering and evaporation, were carried out using clay pots. This method was effective, but not too practical when attempting to produce large volumes of salt. As demand increased, new technologies were developed. Toward the end of the sixteenth century filters were first introduced in Colima. These consisted of wooden platforms with woven branches or sticks supporting several layers of filtering substances. A similar device is still used in Cuyutlán, Colima (Reyes, 1995: 152, 154).

Lake Cuitzeo Basin, Michoacán

There are several thermal springs in the eastern end of Lake Cuitzeo, whose water, which has a high mineral content, is used for the production of salt. Each salt-producing unit (known as *finca*) consists of two or more *estiladeras* (Fig. 2), wooden structures that are used as filters to separate the salt from the earth by leaching. In every *finca* there are several *canoas* (wooden troughs,

Salt Production in Mesoamerica,

Fig. 2 This device, known as *estiladera*, is used for filtering the water from the springs through salty soil to obtain brine by leaching (© Eduardo Williams)

manufactured like dugout canoes; Fig. 3), where the brine that has been filtered in the *estiladera* is evaporated by the sun. Each *finca* has an area of some 50 m² where salt-bearing soils are extracted and mixed. There is also a network of canals that bring water from the springs to the *fincas*, with a depth of ca. 50–80 cm, and several meters in length (Williams, 1999).

The tools used by the saltmakers are quite simple: shovels, hoes, and picks to excavate the soil, wheelbarrows to take it to the *estiladera*, buckets to take the water to the *canoas*. The tools used in the past, however, were quite different: a type of sack made of jute fiber was used to carry the earth, and clay vessels were used to carry the water within the *finca*.

The salt-making process can be divided into four stages: (1) soils are extracted, mixed, and prepared; (2) brine is obtained by leaching the earth in the *estiladera*; (3) brine is evaporated by the sun in the *canoas* and salt is collected; (4) the finished product is packed and sold.

Although the tools and permanent fixtures used today for making salt in the study area are not the same that were employed during the early colonial era, much less in pre-Hispanic times, the basic process for saltmaking still used in this area is in many ways similar to the one described in the sixteenth century *Relaciones Geográficas*.

Salt Production in Mesoamerica, Fig. 3 The *canoas* are shallow troughs made with dugout pine trunks, used in the solar evaporation of brine. Note the crystallized salt on the right, the liquid brine on the left (© Eduardo Williams)

Salt Production in Mesoamerica,

Fig. 4 Filtering device known as *tapeixtle*, used on the coast of Michoacán for leaching estuary water to produce brine (© Eduardo Williams)

Salt Production in Mesoamerica,

Fig. 5 Shallow pools made of sand and lime, known as *eras*. They are used in the solar evaporation of the brine. The *tapeixtle* is in the background, covered by palm fronds (© Eduardo Williams)

Both ancient and modern saltmaking requires extracting the soil, mixing two or more types of earth, adding water, leaching and evaporation (Williams, 1999). Saltmaking in coastal Michoacán is similar to what has been described earlier (Williams, 2002; see Figs. 4, 5, and, 6).

Coastal Guerrero

The process known as *tapeite* in coastal Guerrero, still used in sites such as Tecomate, Chautengo,

and Pozahualco, consists of leaching salt from soils where saltwater marshes dry up during the dry season. The saltmakers carefully break up the thin upper crust of earth and carry it to their saltworks, where they deposit it in a large filter known as *tapeite*, which is constructed on a raised base of wooden or cane slats covered with palm or tough grass. Adobe sides create a rectangular basin lined with coarse sand and a second layer of fine, sifted sand. Brackish groundwater is drawn from a shallow well dug next to the *tapeite* and poured over the saline earth. After seeping

Salt Production in Mesoamerica,

Fig. 6 Harvesting the crystallized salt from the *era*, coastal Michoacan (© Eduardo Williams)

through the filter, the water is channeled into a plaster-lined holding tank. The concentrated brine is poured into the solar drying pans, where it evaporates to leave white granular salt crystals (Good, 1995, p. 2).

The Maya Area

Salt was a regional necessity everywhere in Mesoamerica, yet the white salt of Yucatán was also a bulk luxury, traded far beyond the regional level. Flowing from international trading centers to regional markets in foreign territories, it augmented regional supplies as a product of superior quality (Kepecs, 2003, p. 129). The pre-Hispanic Maya obtained salt from several sources, the most abundant ones being the coastal saltworks. The primary source of salt in pre-Hispanic Mesoamerica was coastal Yucatán, where salt was obtained through solar evaporation. Archaeological evidence shows that Yucatecan saltworks were active from the Late Formative (ca. 300 BCE–AD 300). In colonial times salt production in Yucatán was approximately 20,000 tons per year, enough to satiate the needs of several thousand people, or the whole of the Maya Lowlands through history (Andrews, 1997, p. 40). Salt was scarce in the southern Maya lowlands of Guatemala and Belize. It was

imported in bulk from the north coast of Yucatán, although recent fieldwork has documented closer sources of salt than those of the north coast (Mc Killop, 2002).

A method for making salt which is still found in a few sites near the Chiapas coast is the one known as *tapesco*. It involves leaching marsh soil with estuary water which is then evaporated in small solar pans. The *tapesco* salt-making operation takes place mainly during the dry season (from January to May or June). The soil to be leached is raked up and placed on raised wooden structures known as *tapescos*, the bottom part of which consists of a three-layered filter made of thin sticks covered with grass reeds, which in turn are covered by a thin layer of sand. Salt water is drawn from small shallow wells and poured over the soil in the *tapesco*, thus leaching the soil. After passing through the filter the water collects in a mud-lined pan beneath the *tapesco*. The brine is then placed in a series of small shallow solar evaporation pans, where evaporation takes place anywhere from 4 to 6 days, depending on available sunlight (Andrews, 1983, pp. 62–63).

Veracruz

During the Early Formative (ca. 1200–900 BCE) in El Salado, Veracruz, solar evaporation in

pottery trays was the primary method of salt production. This method was supplemented by some saltmaking involving boiling brine. During the late Classic (ca. AD 600–900) brine reduction involved a two-step process whereby salt content in the brine was first increased by boiling in pots; this brine was later reduced to loaves by boiling over fire in shallow ceramic basins (Santley, 2004).

Sāmanta Candrasekhara

Manu V. Devadevan

Archive India Institute, Bhubaneswar, Odisha, India

Sāmanta Candrasekhara Siṃha (1835–1904) was a nineteenth-century astronomer from Eastern India. Popularly known as Paṭhāṇi Sāmanta, he was the last great exponent of traditional Indian astronomical knowledge and the author of *Siddhānta Darpaṇa*, the longest Indian text on astronomy.

Candrasekhara was born in 1835 at Khaṇḍapāḍā in the Nayagarh district of Odisha. He belonged to a princely family that had fallen on bad days and grew up in poverty with no exposure to formal education or modern science. Although he received his first tuitions in astronomy at the age of ten from an uncle, Candrasekhara was a self-taught astronomer who put his knowledge of Sanskrit to good use in studying the palm-leaf manuscripts on astronomy that he could access. How many works he could lay hands upon is not clear, but his proficiency in the *Sūryasiddhānta* and Bhāskara II's *Siddhānta Śiromaṇi* is well attested. By the age of 35, he had earned a reputation for himself among the intelligentsia of the region. The king of Puri conferred on him the title of Haricandana Mahāpātra in 1870. The British honored him with the title of Mahāmahopādhyāya in 1893. It is now customary, among enthusiasts and scholars alike, to refer to him as

Mahāmahopādhyāya Sāmantha Candraśekhara Siṃha Haricandana Mahāpātra.

Not much is known about Candraśekhara's life, which seems to have been mostly woeful. On the day of his wedding, the bride's parents called off the alliance, and although they were persuaded to change their decision, the marriage turned out to be unhappy. Five sons and six daughters were born of the marriage. The local ruler, a cousin of Candraśekhara, expelled him from Khaṇḍapāḍā over a personal dispute. Candraśekhara could return to Khaṇḍapāḍā only after the intervention of a senior British official, the Commissioner of Cuttack. He died in 1904 in Puri while on a pilgrimage.

Candraśekhara was convinced, even as a boy of 15, that many of the prevalent astronomical calculations in India needed serious revision. He discovered that texts like the *Sūryasiddhānta* from which he learnt the basics of astronomy were also not always reliable. He resolved to change this state of affairs and began observations, for which he built a number of instruments ingeniously, some of which are now preserved in the planetarium at Bhubaneswar in Odisha. The instruments included an armillary sphere, a gnomon, and a vertical wheel. The gnomon carried a mirror, which enabled measurement of time and angular distances even at night. Candraśekhara also used a water clock to measure sidereal time. An important instrument he devised on his own was a T-square (which he called the *mānayantra*), which had a 24-digit main limb and a crosspiece bearing notches with holes made at distances equal to the tangent of the

angles subtended at the free end of the main limb. He also made a wheel (which he called the *svayaṃ vāhaka*) that moved on its own with the help of spokes filled with mercury. After eight years of observation, he began to work on the *Siddhānta Darpaṇa*, which he completed in 1869. There are indications in this work that it was revised, perhaps at regular intervals. With 2,500 verses spread across five sections and 24 chapters, the *Siddhānta Darpaṇa* is among the greatest magna opera in Indian astronomy. The levels of perfection he achieved were not only due to his sophisticated use of instruments but also due to other factors like a better model of the planetary system and his ability to measure and correct all three errors in the lunar motion. One of Candraśekhara's major achievements, for which he is known among the orthodox literati of Odisha, is that he carried out major revisions to the *Jagannātha Pañji*, an influential traditional almanac of Odisha maintained by the Jagannātha temple of Puri. This almanac, which apparently owes its origin to Śātānanda's *Bhāsvatī*, circulated in an extremely corrupt form as no corrections had been carried out for a long time.

Candraśekhara followed a geocentric planetary model in which the planets Mercury, Venus, Mars, Jupiter, and Saturn moved around the sun and the sun, in turn, around a static earth. This was very similar to the model developed by Nīlakaṇṭha Somayāji in Kerala in the fifteenth century. Candraśekhara also adopted 3,927/1,250 or 600/191 as the value of π , instead of the popular 22/7. His observations and calculations yielded results that were often closer to their modern

Sāmantha Candraśekhara, Table 1 Inclinations of the orbits of planets to the ecliptic, based on Naik and Satpathy (1998)

Planet	According to Sūryasiddhānta	According to Siddhānta Śiromaṇi	According to Sāmantha Candraśekhara	European value in 1899	Modern value
Moon	4° 30'	4° 30'	5° 9'	5° 8' 48"	5° 8' 33"
Mars	1° 30'	1° 50'	1° 51'	1° 51' 2"	1° 50' 59"
Mercury	5° 55'	6° 55'	7° 2'	7° 0' 8"	7° 0' 18"
Jupiter	1° 0'	1° 16'	1° 18'	1° 18' 41"	1° 18' 18"
Venus	2° 46'	3° 6'	3° 23'	3° 53' 35"	3° 23' 41"
Saturn	2° 0'	2° 40'	2° 29'	2° 29' 40"	2° 29' 10"

value, as the following table on the inclinations of the orbits of planets to the ecliptic, based on Naik and Satpathy (1998), confirms (Table 1).

One of Candrasekhara's outstanding achievements was his observation with his naked eye of the 1874 transit of Venus. He found that during "the eclipse of the Sun by Venus," the shadow of Venus was 1/32 of the shadow of the Sun. The accuracy of this naked eye observation is simply astonishing. This was when the influential journal *Nature* was reporting the observations made by Norman Pogson from the Madras Observatory and by E.W. Pringle from Mananthavady in Kerala, the latter using a sophisticated Cooke refracting telescope. It is rather unfortunate that Candrasekhara does not tell us anything about the method he adopted to arrive at this finding. We also do not know if he was aware of the 1882 transit of Venus (which, however, was not visible in India).

Samarāṅganāsūtradhāra

Mattia Salvini

Mahidol University, Nakhon Pathom, Thailand

The *Samarāṅganāsūtradhāra* (SSD) is a complex and vast text that brings together a catalogue of heterogeneous topics, all directly or indirectly related to the thematic heading of Vāstu – a building site. The work is associated with the name of Bhoja, the Paramāra king, who is likely to have been its (partial) author and/or patron and inspirer. Considering the plausibly layered composition, the text's date may be best described by saying that some of its strata should have been coeval with Bhoja himself (eleventh century); also, the text seems to contain materials related to architectural practices that predate Bhoja.

The title of the work can be interpreted and translated in more than one way (multiple meanings being a virtue in the literary world of South Asia). "Stage Manager of Battlefields" and "Architect of Human Dwellings" are two plausible renderings for *Samarāṅganāsūtradhāra*, and thus, the title well captures the idea of a text on Vāstu authored and/or patronized by a powerful ruler.

The SSD offers an origin story that shows the close connection between the birth of the universe and the necessity of Vāstu as a branch of knowledge (*śāstra*). Since Vāstu is devoted to the sensible and beneficial organization of human dwellings, it becomes an indispensable tool for rulers to distribute human types and activities through their domains and palaces. In other words, the SSD presents Vāstu as the fundamental treatise on regulating human activities through the land. Vāstu is the technology through which

palace, and it is instructive to compare the available archaeological evidence with the SSD's sections on the king's palace and its layout. Similarly, Adam Hardy has offered a compelling visual translation of the SSD's instructions on temple architecture. What comes to light from these comparisons is that the SSD does work as a manual for actual building practices, and yet it leaves much unsaid. This too suggests that the text was employed within a broader context of training and oral instruction.

Linguistically, the SSD is in rather regular, well-written Sanskrit (except for a few, still easily comprehensible, features). One of the difficulties in understanding the treatise is the flexible use of terms and synonyms regarding measures, and some uncommon grammatical formations to express numbers and fractions. The editorial state of some sections makes it difficult to obtain a complete and reliable picture of what is being described; in some cases, though, the "architectural logic" of the passages is consistent enough that filling the blanks seems plausible.

The SSD presents itself as a vast and ambitious intellectual project. The world, including its origin and purpose for mankind, is retold and re-catalogued from the privileged perspective of Vāstu (the science of human and divine dwellings). To do so, this Vāstu treatise weaves in elements of Purāṇic and Sāṃkhya cosmology, cosmogony, and physical theories, and concludes (if indeed the text was ever closed) with the outer layers of the temple, where the depiction of dance and their suggested aesthetic flavors finds a place.

Samū'īl ibn 'Abbās (Al-Maghribī)

E. Ruth Harvey

Samū'īl (or Samau'al) ibn 'Abbās, also called Abū Nasr Samū'īl ibn Yahyā ibn 'Abbās, was a Jew whose father's family origins were in Fez in Morocco. Samū'īl is often called al-Maghribī, "the westerner," but he spent his life in Iraq, Syria, Kurdistan, and Azerbaijan, and died in Maragha in about 1175 (570 AH). He was famous as a mathematician and physician, and left a number of works on both subjects. In 1163 he underwent a conversion to Islam and subsequently wrote a polemical treatise against the Jews; in an autobiographical appendage to this work he provided a very interesting account of his careful upbringing, extensive education, and the dreams which prompted his conversion. Samū'īl practiced medicine at Baghdad (where he wrote some of his works) and Maragha (where he served a number of local princes and important personages).

The early Arab biographers ascribe many works to Samū'īl, but not all of these are extant. Steinschneider and Brockelmann list 17 treatises, some of which are works not mentioned by the biographers but which are ascribed to Samū'īl in manuscript; some attributions are doubtful.

The only extant medical treatise attributed to Samū'īl is an elaborate work on sex and gynecology entitled *Nuzhat al ashāh fī mu'āsharat al-ahbāb* (The Entertainment of Friends and the Dealings of Lovers), often referred to in catalogs as *De Coitu*. Works of this kind are not infrequent

in the Arabian medical tradition; Samū'īl's treatise was written for the ruler of Hisn Kayfa, Muḥammad ibn Qara Arslan, and was famous enough to have survived in a number of widely scattered manuscripts; it has never been printed. An account of the work may be found in Leclerc. It contains two books. The first deals with sex, both homosexual and heterosexual, sexual desire, diet, and hygiene; it contains an account of the physical and moral characteristics of women from different countries. The second book deals with such topics as impotence, aphrodisiacs, conception, sterility, and female ailments. There are manuscripts in Paris, Berlin, the Escorial, I Leipzig, and Istanbul. The Berlin catalog lists (in Arabic) all the chapter headings of the *Nuzhat*.

Some of the treatises on mathematical subjects ascribed to Samū'īl by the early biographers are no longer extant, but copies of his *al-Tabsira fī 'ilm al-ḥisāb* (Introduction to Arithmetic) survive. Both Leiden and Oxford have manuscript copies of a work entitled *Fī ṭī kashf' awar al munajjimīn* (On the Errors of Astronomers), in which Samū'īl defends the idea of scientific progress, citing an arithmetical work of his own, *Al-bahir*, as an example of an advance on ancient mathematics. Brockelmann says that a manuscript of a work entitled *Al-bahir fī 'ilm al-ḥisāb* attributed to Samū'īl exists in Istanbul; perhaps this is the one referred to in *Errors of the Astronomers*. Another work on arithmetic, *Al-mujiz al-mardawi fī al-ḥisāb*, also exists in a single manuscript in Istanbul.

The Arabic text of Samū'īl's polemic against Judaism, *Ifhām al-Yahūd* (Silencing the Jews), together with his autobiographical addition, has been edited and translated into English by Perlmann, who provides in his introduction the best account of Samū'īl and his works. Perlmann points out that the work *Al-Ajwiba alfakhira raddan' an il-milla al-kafira* ascribed to Samū'īl by Brockelmann derives from Samū'īl's work but is not by him. Another polemical work against the Jews, the *Contra Judeos* of Samuel Marochitanus which was translated from Arabic into Latin in 1339, has often been ascribed to Samū'īl ibn Abbas; it contrasts Judaism unfavorably with

Christianity, not Islam, and is clearly the work of another author.

Śaṅkara Vāriyar

K. V. Sarma

Madras, Tamilnadu, India

Śaṅkara Vāriyar (ca. 1500–1560) was a brilliant expositor of astronomy and mathematics who hailed from Kerala in the south of India. He belonged to the *vāriyar* community, which was professionally assigned to certain peripheral duties in temples. Śaṅkara was a direct disciple of the well-known Kerala astronomer Nīlakaṇṭha Somyāji (b. 1444). Among other teachers whom he mentions in his works are Dāmodara (ca. 1450–1550), Jyeṣṭhadeva (ca. 1500–1610), and Citrabhānu (ca. 1475–1550). Śaṅkara

mentions that his commentary on the work *Pañcabodha* was completed on the day 1,692,972 of the Kali era, which occurs in AD 1534, from which his date is definitely ascertained.

Śaṅkara Vāriyar wrote an advanced astronomical manual entitled *Karaṇasāra*, to which he added a gloss of his own. But he is better known for his elaborate commentaries on such standard works as the *Līlāvātī* of Bhāskarācārya, the *Tantra-saṅgraha* of Nīlakaṇṭha Somayāji, and the anonymous *Pañcabodha*. The two commentaries, the one on the *Līlāvātī* called *Kriyākramakarī* (Sequential Evolution of Mathematical Procedures) and that on *Tantrasaṅgraha* called *Yuktidīpikā* (Light on Astronomical Rationale), are highly significant writings in Indian mathematical literature. After giving the meaning of each textual verse or group of verses from these two texts, Śaṅkara sets out the background and evolution of the enunciation commented on, the different aspects thereof, and the step-by-step derivation of the relevant formula or procedure. This exposition of rationale, couched in simple verses and often running to several pages, serves to give an exposure to Indian mathematical thinking and open up the normally unexpressed mental working of the Indian mathematician, which has led most modern historians of mathematics to presume that much of Indian mathematics and astronomy was borrowed and not original. The rationale elaborated here relates, among other things, to the summations of series; the circle and the irrationality of π and pulverization in the field of mathematics; and the theory of epicycles, ascensional differences, rising of the signs, and problems based on the gnomonic shadow in astronomy. These commentaries are valuable also for the information on earlier authors like Mādhava and Saṅgamaṅgrāma and their theories.

Santería

Johan Wedel

School of Global Studies, University of
Gothenburg, Gothenburg, Sweden

Santería has its roots in the slave trade when a large number of slaves were taken from Africa to Cuba. Many were from the Yoruba people, who now live in southwestern Nigeria. The Yoruba, well known for their artistic traditions, urban lifestyle, and a well-developed division of labor, brought with them a belief in their divinities, *orishas*. In Cuba, the *orishas* merged with the saints of the Roman Catholic Church, which, in turn, led to the creation of santería, “the way of the saints” (Brandon, 1993; Cros Sandoval, 2006; Lawal, 1996; Matibag, 1996; Murrell, 2010; Thomas, 1997; Thompson, 1983; Wedel, 2004).

Only a handful of the more widely recognized *orishas* survived the Middle Passage. As the divinities acquired their Catholic equivalents, they became to be known as *santos* – saints. Oshún, for example, the *orisha* of fresh water, acquired a Catholic equivalent in the form of Virgen de la Caridad del Cobre. Shangó, the manly warrior who represents thunder, lightning, and fire, found a counterpart in the Catholic saint Santa Barbara. Apart from these two popular divinities, some of the most prominent

orishas/santos include: Eleggua, messenger and guardian of crossroads; Ogún, lord of war and iron; Obatalá, father and lord of peace and purity; Yemayá, mother and ruler of the seven seas; and Oyá, female warrior, guardian of the cemetery, who is associated with strong winds.

The actions and adventures of the divinities appear in the many santería myths (*patakies*), which, in turn, are related to various kinds of divination systems (Martínez Furé, 1979; Pérez Medina, 1998; Valdés Garriz, 1997). In one myth, the supreme god Olodumare-Olofi first created the universe and then distributed his *ashé*, life force, to the orishas/santos. As humans develop their relationship with the divinities through rituals and sacrifices, they benefit from the *ashé* that came from the high god Olodumare (Figs. 1 and 2).

In Cuba today, as well as in other Latin American countries and in the United States, people frequently turn to santería for all kinds of problems. Illness, however, is a particularly common reason for consulting a priest (see also Jones et al., 2001; Pasquali, 1994; Sandoval, 1979, 1995; Wedel, 2004). Using divination, the priest will relate the client's problems to the santería mythology and a number of proverbs. The priest (*santero* or *santera*) uses cowrie shells when divining with the dilogún divination system, while the high priest (*babalao*) uses a chain made of coconut shell or tortoise shell when divining with the Ifá system (Bascom, 1952, 1980; Mason, 1993; Matibag, 1997; Valdés Garriz, 1997; Wedel, 2004). It takes many years of training to become a skilled diviner. A *babalao* is considered "mature" after working and

Santería, Fig. 1 Eleggua, guardian of crossroads, is represented by a "head" of cement with eyes and mouth made of cowrie shells, while Ogún, lord of iron, is represented by a cauldron with iron tools (Photo by Johan Wedel)

Santería, Fig. 2 When sacrifice is performed, *ashé*, divine force, is released. The santería objects are then covered with feathers from sacrificed fowls in order to "cool" the "hot" blood (Photo by Johan Wedel)

divining for 16 years (Wedel, 2004, p. 92; Wirtz, 2007).

Once the priest has identified the client's condition through divination, spiritual cleansing, offerings, sacrifices, and minor rituals are commonly suggested. Santería priests usually have extensive knowledge of a multitude of herbs and plants, and some of these may also be recommended (Brandon, 1991; Cabrera, 1993; Marks, 1987; Wedel, 2004). In the case of an illness, clients are often told to pay a visit to a physician. From the perspective of santería, however, it is not sufficient to try just to cure the affliction; the underlying reasons for the problem must also be identified. The priest will also explain why a person has been struck by ill health and may attribute the problem to a lack of *ashé*, to afflicting spirits, to disturbed social relations and sorcery, or to the client's lifestyle (Wedel, 2004; Fig. 3).

Santería, Fig. 3 Sacrifice of a goat during an Afro-Cuban quasi-religious ceremony in the street Callejon de Hamell, Central Havana (Photo by Johan Wedel)

In santería, it is recognized that both physical and mental illnesses are frequently related to disturbed social relations, and these are expressed in terms of sorcery (cf. Stoller & Olkes, 1987; cf. Geschiere, 1997). An envious neighbor or family member, for example, might be said to have performed sorcery on the client (although the priest seldom reveals the name of the evil-doer). The client may then be advised to break up a relationship, move to another house, change jobs, or avoid certain persons in order to become well. An affliction may also be caused by a spirit or divinity who wants the person to change his way of life and become a practicing priest (Wedel, 2004).

When divination discloses a serious illness and it is established that medical treatment will not be adequate, initiation may be recommended. This was expressed by a Cuban *babalao* who also works as a physician, who said: "We do this when modern medicine can do no more, when you reach the limits of science" (Wedel, 2004, p. 121). A similar opinion was articulated by another *babalao*: "We religious people say that sometimes a person has to attend *el brujo blanco* [the 'white sorcerer'] who is the [biomedical] doctor. Sometimes he has to attend *el brujo Yoruba* [the 'Yoruba sorcerer'], who is the *santero* or *babalao*" (121) (Figs. 4 and 5).

Initiation into santería, which also may take place for reasons other than illness, is a "rebirth," a gradual process designed to change a person's experience and transform the whole lifeworld of the devotee (cf. Turner, 1969, 1986; cf. Clark, 2007; Wedel, 2004; cf. Willis, 1999). The "new-born" builds a beautiful altar for his/her personal divinities (Brown, 1996, 2003; Flores-Peña & Evanchuk, 1994) and is kept in isolation for seven days, while a godmother or godfather feeds and cares for them. The initiate is also given *omiero*, a mixture of secret herbs said to contain large quantities of *ashé* (Brandon, 1991).

During the initiation, which is largely secret and closed to the noninitiated, a divinity will be "placed in the head" of the initiate. This *orisha/santo*, who is said to be the "father" or "mother" of the initiate, will then offer its protection for the rest of the initiate's life. The initiation also

Santería, Fig. 4 Osain is the lord of herbs and plants. He is represented by a calabash with powerful, secret herbs, which is hung from the ceiling. If a menstruating woman comes into contact with the calabash, it will lose its power (Photo by Johan Wedel)

Santería, Fig. 5 Afro-Cuban objects arranged by the artist Salvador Gonzalez at Callejon de Hamell, Central Havana (Photo by Johan Wedel)

involves a complex divination session, including ritual cleansing, animal sacrifices, offerings to the dead ancestors, and dancing to the sacred santería drums. During the drum ceremony, the divinity may “descend” into the body of the novice, who

may experience possession trance (cf. Goodman, 1988, 1990; cf. Clark, 2007; Murphy, 1993, 1994; cf. Turner, 1992; Wedel, 2004; cf. Willis, 1999).

For one year after the initiation, everyone will address the initiate as *iyabó*. He/she is close to the divine world of the *santos/orishas* and must obey certain rules, such as wearing white clothes and not visiting cemeteries. The initiate will also acquire new social relations and become a “sister” or “brother” to others who have been initiated by the same godmother or godfather. Through initiation, an intimate relationship between humans and the world of the *orishas/santos* is created, and the initiate develops a new understanding of what has caused the affliction and how to avoid problems in the future.

Śatānanda

Manu V. Devadevan
Archive India Institute, Bhubaneswar, Odisha,
India

Śatānanda was a widely respected eleventh-century astronomer from the city of Purusottama

(now Puri) in Odisha. The son of a certain Śaṅkara, he was the author of the *Bhāsvatī*, an influential treatise on the making of almanacs. This work was completed in the year 1099–1100 CE (Śaka 1021).

By the year 1099–1100, Anantavarman Coḍagaṅga, the founder of the Western Gaṅga state, had established sway over large parts of coastal Odisha. He ruled for 70 long years from 1077 to 1147 CE. He was instrumental in redefining the political and religious life of the region in many ways. Today, his fame rests largely on the fact that he rebuilt the temple of Puruṣottama (Jagannātha, since the fourteenth century) in the town of Puri. We owe much of the political and religious legacy the region inherited in the coming centuries to this great pioneer. There are no historical documents to suggest that Śātānanda was Anantavarman's protégé. Nevertheless, this is not unlikely. The fact that his *Bhāsvatī* was regarded as the preeminent text on almanac making in eastern India and many parts of north India for several centuries seems to suggest that he was closely associated with the Jagannātha temple. A number of manuscripts of the *Bhāsvatī* have been retrieved from these regions. It is available today in many recensions, some of them carrying a follow-on called the *Uttara Bhāsvatī*. The *Bhāsvatī* was widely commented upon during the period between the fifteenth and the eighteenth centuries. Most of these commentaries have been obtained from eastern and parts of northern India. These include Aniruddha's *Śiṣubodhinī* (1495 CE), Mādhava's *Mādhavī* (1525 CE), Acyuta's *Ratnamālā* (ca. 1525 CE), Kubera Miśra's *Ṭika* (1685 CE), and Rāmakṛṣṇa's *Tattvaparakāśikā* (1739 CE).

Śātānanda expresses his debt to the *Sūryasiddhānta* and states that his work is based on its summary contained in Varāhamihira's *Pañcasiddhāntikā*. This, it is believed, is implicit in the name of his work, *bhāsvan* being a synonym for *sūrya* (the sun).

The *Bhāsvatī* is a short work of 82 verses, divided into eight chapters. It is different from other Indian texts on astronomy in many respects. First, works on astronomy generally give the epochal constants for the city of Ujjayini, but

the *Bhāsvatī* records it for the town of Puri. Second, its computation of Mean planets was based on the *varṣagaṇa* (number of years elapsed) and not the *ahargaṇa* (number of days elapsed). Third, the commencement of the year was recorded in terms of True *meṣādi* (Aries ingress) and not the Mean *meṣādi*. Fourth, Śātānanda's work adopted the centesimal system for the commencement of epochal positions and for specifying multipliers and divisors. Fifth, it stated the position of the sun and the moon in terms of *nakṣatras* (constellations) and not *rāśis*. Sixth, the *Bhāsvatī* identified 528 CE as the zero-precision year and determined the rate of precision as being 1 min per year. Śātānanda's methods became so powerful that the *Bhāsvatī* was widely used for centuries, especially due to the belief that eclipses calculated on its basis would always be marked by great precision.

Science and Spirit

Nitin Trasi

The word “spirit” is derived from the Latin *spirare*, to breathe, or *spiritus*, breath. The term “spiritual” is sometimes taken to mean matters

concerning the supernatural or the occult. However, the true meaning of the word concerns matters pertaining to the spirit, the animating principle in man, as opposed to matters pertaining to the physical and material. Thus “spirituality” in Sanskrit is *adhyātma*; in Pali, it is *ajjhat*.

The true spiritual quest in the most rigorously scientific sense of the term would then mean research into consciousness itself. Although India has had its fair share of occultists and those interested in the paranormal, a significant contribution of India to the world, from ancient times down to the modern age, has been the remarkable research into the nature of consciousness. Right from the Vedic times, the seers of India have been interested in questions about life and its meaning and in consciousness itself. Who are we? Where do we come from? What is the nature of the consciousness that animates us? What is its source? Is there an unchangeable ultimate reality or first principle in life? What is the cause of human suffering, and what is its solution? These and other fundamental questions have engaged their attention. These men have conducted scientific research into consciousness, in which they have explored the mind and the inner world within man himself. They conducted thought experiments and delved deep into their own minds and thinking processes to seek out the basic truths about life, consciousness, and the universe.

Vedānta

The four *Vedas* are the most ancient sacred literature of India. They were probably composed over several centuries during the second millennium BCE. The early Vedic hymns contain extremely detailed poetical descriptions of nature, and speculations about the origin and nature of the universe. The *ṛg-Veda* declares, “Who verily knows and who can here declare it, whence it [the universe] was born and whence comes this creation?” (Nikhilananda, 1997). And before this creation? “There was neither existence nor nonexistence then, neither air nor the sky beyond...neither death nor immortality,

night nor day...darkness was concealed in darkness there!” (*ṛg Veda*, III.129.1–3).

Deities symbolized the different forces of nature, but even in these early hymns, there is an awareness of the unity of these deities. “They speak of Indra, Mitra, Varuṇa, Agni, [names of deities]...the One Reality the sages call by many names.” (*ṛg Veda*, I.164.46, *Atharva Veda*, IX.10.28). “In That all this unites, from That all this emerges. The all-pervading One is the warp and woof of all created things.” (*Yajur Veda*; *Vājasneya Saṁhitā*, 40.1).

Though the earlier parts of the *Vedas* (the *Karmakāṇḍa*, the ritualistic section) dealt more with means to derive health, wealth, and material prosperity, later on the approach changed, as it was realized that these benefits were all transitory and subject to corruption with time. It is in these latter parts (the *Jñānakāṇḍa*, the knowledge section) that the *Vedas* really begin to deal with the question of lasting peace and happiness and the nature of consciousness itself. The concluding portions of the *Vedas* are called the Vedānta (*anta*: end, essence) and include the treatises called the *Upaniṣads*, which date back to the last millennium BCE. There are 108 *Upaniṣads*, of which 11 are considered the most important.

The Knower

In the *Upaniṣads*, the approach is highly introspective, and a critically important distinction is made between the “seer” (*dṛk*) and the “seen” (*dṛṣya*). Through a lot of intricate discussion, it is shown that the seer is the unchangeable Consciousness or the knowing principle that cannot be recognized easily, because it is itself attempting to do the seeing or knowing. Just as the eye cannot see the eye, the seer cannot know itself as an object. “How can one know that by which all this is known?” (*Bṛhadāraṇyaka Upaniṣad*, IV.5.15). And yet, itself the knower, who else is there to know it? The seer or the knower is in reality the innermost consciousness within us, the *ātman*, “the light of lights which is my inner being” (*Yajur Veda*; *Vājasneya Saṁhitā*, 34.1–3). Since whatever it can perceive

(the seen or known) cannot be itself (the seer or knower), it therefore has to resort to elimination to recognize itself – a process symbolized by the famous words, *neti, neti* meaning, “It is not this, it is not this” (*Bṛhadāraṇyaka Upaniṣad* II.3.6). The ātman is finally said to be able to recognize itself only through intuitive knowledge and it is therefore said to be *svasākṣi* (self-cognized) (*Vivekacūḍāmaṇi*, 216). This knowing is not an objective but an intuitive knowing, “just as one knows of one’s own existence even without the aid of a mirror” (*Amṛtānubhava*, II.76).

The Ultimate Reality

The idea of a single ultimate reality (*Brahman*), the basis of the physical universe appears early in the *Vedas*: “I know the drawn out thread in which all these creatures are strung. I know the thread’s thread. I know the great *Brahman*” (*Atharva Veda*, X.8.38). But it is the *Upaniṣads* that elaborate on the details of this monistic idea of a single reality *Brahman* manifesting as the universe and its diverse objects, including human beings – the doctrine of *advaita*, monism. “Ever unborn, He is born in many forms. In Him alone reside all living things” (*Māhānārāyaṇa Upaniṣad*, 1.2). The relationship of the individual consciousness with this Reality is also stated. The ātman, the individual source of consciousness within a person, is not different from *Brahman*, the Universal Consciousness, but only appears to be separate because of the limiting adjuncts of the body and mind. The conclusion is finally reached that this (apparent) sundering from that reality is the true cause of insecurity and suffering in life, and reunion (or rather recognition of the essential oneness) with that reality is the only way to lasting, unqualified peace.

The Scientific Approach

Throughout the *Upaniṣads*, the approach is always investigative, and never dogmatic. The Truth is mentioned, but the pupil is expected and encouraged to question it and confirm it for himself, by his own efforts. The criteria of truth

are said to be not just *śruti* (scriptural authority), but its conjunction with *yukti* (reasoning) and *anubhava* (experience) (Nikhilananda, 1997, p. 17). “The true nature of things is to be known personally...and not through a sage. What the moon exactly is, is to be known with one’s own eyes; can others make him know it?” (*Vivekacūḍāmaṇi*, 54).

Monism was therefore not the only doctrine that was existent, though it was the dominant one. The spirit of enquiry dominated philosophical thought (*darśana*) both in ancient and medieval India, and a wide spectrum of philosophical ideas was explored. At one extreme of this diverse spectrum was the purely materialistic doctrine of the pre-Buddhist Cārvāka school, which approximated to pure hedonism. There were also the Pūrva Mīmāṃsa of Jaimini, the Uttara Mīmāṃsa ascribed to Vyāsa, the Sāṃkhya of Kapila, Patanjali’s Pātāñjala, Gautama’s Nyāya, and the Vaiśeṣika of Kānada. At the other extreme was the *bhakti* (devotional) tradition, with its total emphasis on love of God. But even within this devotional tradition, a variety of philosophical thought was expressed, and (apart from monism) there were several doctrines to explain the relationship of the human with the Divine. The *dvaita* (dualism) school taught that the soul (or self) and God are eternally separate. Its most important proponent was Mādhvācārya, a mediaeval philosopher and religious teacher of South India. The school of Viśiṣṭa Advaita (qualified monism) of Rāmānuja (eleventh century AD, South India), stated that the individual souls were very close to God and a part of him, but not one and the same (“like seeds in a pomegranate”); while the Śuddha Advaita doctrine (“pure” monism) of Vallabhācārya of mediaeval India made a fine distinction between the individual souls and God, saying that they are related “as sparks to a fire.”

Advaita and Science

Science and religion do not always agree with each other. Religion is generally a matter of faith, whereas science depends upon plausible theories and empirical confirmation.

Advaita seems to offer a model of spirituality which agrees with science on these points. In this philosophy, there is no separate individual soul (there is only an illusion or appearance of a separate self or soul). The reality of God according to this theory is that he is the Universal Consciousness, the Source or Ground of all being, and not a personal, anthropomorphic, all-powerful entity. And finally, these things are definitely not asked to be accepted on trust. The individual is encouraged to find out for himself and confirm and corroborate these findings on his own.

Thus advaita presents to the world perhaps the most elegant, the most feasible, and the most scientifically acceptable of all theories of ontology. Advaita has also been shown to be closest to the new physics and quantum mechanics (Capra, 1976; Goswami, 1993).

Bhagavad Gītā and Karma-Yoga

Probably originally composed in about 1500 BCE, the Bhagavad Gītā is considered to be as authoritative as the *Vedas*. The philosophy in the *Bhagavad Gītā* (BG) is generally consistent with the advaitic tradition, though like the *Upaniṣads*, the followers of the non-advaitic traditions interpret it differently. However, its most important scientific contribution to the world is the thoroughly practical philosophy of *karma-yoga* (lit. the art of action, BG: II-50). Consistent with modern management principles as well as modern psychology, karma-yoga teaches an attitude to be adopted toward everyday duties and actions. Excessive concern about results interferes with the efficiency of the activity. Specifically, karma-yoga suggests performing action without worrying unduly about the results – *karma-phala-tyāga* (lit. surrender of the fruits of action) (BG, II.47–48, XII.8–11).

Buddhism

The Buddha

Whereas a large part of Vedāntic philosophy involved intricate discussions on consciousness,

the Buddha (sixth century BCE) took a refreshingly different approach. At a young age, the Buddha, then Prince Siddhartha Goutama, was deeply disturbed by what he saw as the terrible inevitabilities of life: suffering, old age, and death. Desperately seeking a solution, and dissatisfied with the answers the scholars offered, he set out to discover the truth on his own. Rejecting all authority, discarding all theoretical speculation, he struggled for many years until 1 day, illumination dawned upon him. The Buddha spent the rest of his life spreading his message, until he died at the age of 80.

The Buddha proposed that ordinary human existence is an unsatisfactory state in which people make themselves miserable as a result of a basic misunderstanding of their own nature, and that there exists another way of being in this world, *nirvāṇa* (*nibbāna*), which is a release from this misery. Nirvāṇa is not some superhuman state, but rather a natural way of being, accessible to any human being. The way to nirvāṇa does not require acquisition of special powers, nor withdrawal from life or any other extremes. It is therefore called the “middle way.”

The Buddha decried appeals to authority or tradition. He proposed a highly scientific, completely empirical approach, without recourse to any pre-existing theoretical concepts. He offered no theory of God and discouraged all speculation on the subject, and restricted himself to purely practical teaching. Based upon a systematic rational analysis of the problems of life, his teachings offered a way to their solution. A psychologist and a philosopher, he formulated his own experiential techniques to study the mind.

The Buddha’s teachings include a set of concepts of how the mind works – the oldest psychology of which the world has any record (Anderson, 1979, p. 5). In the Buddhist view, the person is seen not as a solid reincarnating entity, but rather as a flow of mental processes. At any one time, a human being is an aggregation of events, and that aggregation is constantly changing. There is thus no identifying essence at the core of any human being – no eternal soul, no *jīvātman*. In other words, the “me” is

not a person, but a process, and that process is in a state of constant flux, like a flowing river. This is the principle of *anātman* (no-soul). However, this concept of no-self is most definitely not a dogma. The correct Buddhist position is not to hold any dogmatic views, but rather to see things objectively as they are without mental projections (Anderson, pp. 29–31).

The Buddha is also said to have formulated and taught a detailed step-by-step practical technique to approach the realization of the state of *nibbāna*. This technique is called *Vipaśśanā*.

The Technique

Vipaśśanā means knowledge by seeing, clear perception. It means to observe reality in the right way – as it is, and not as it appears to be, colored by belief and imagination (Goenka, 1994). The *Vipaśśanā* technique is a type of meditation – an observation-based, self-exploratory journey into one's own mind.

Vipaśśanā meditation trains the concentrated attention to follow the mechanics of mental processing with the base of concomitant physical sensations, in a detached fashion (Fleischman, 1986). As the sensations arise and pass away, the wisdom of impermanence arises in the mind (everything is impermanent – *anicca* – nothing is eternal) and one attains equanimity amidst life's vicissitudes. The mind is gradually deconditioned (Goleman, 1977), and life becomes characterized by increased awareness, reality-orientation and peace (Fleischman). Man is led away from narcissism to mature, social love, and this personal transformation becomes the catalyst for social change and development (Fleischman, 1991).

Mindfulness

Vipaśśanā consists ultimately in arriving at a state of mental alertness or attentiveness to the present, both with respect to the outer world, as well as to the inner – the workings of the mind. It is an ongoing process and results in enhanced insight and psychological maturity, as well as equanimity. The spontaneous (not enforced), easy state of mental alertness or awareness which results is known as *sati* (mindfulness), and could be

described as a prospective, ongoing awareness of thought and action (as opposed to analysis – which is retrospective deliberation).

Buddhist mindfulness practice has some strong similarities to Gestalt therapy of Western psychology. Both emphasize the *how* of life rather than the *why* (unlike Freudian psychoanalysis). Repression of feelings is not advised, nor is change through inner or outer coercion. Emphasis is on being attentive, perceiving the truth, and being free. As in Gestalt therapy, *Vipaśśanā* meditation involves focusing on the actual, reduction of conceptual activity, and noninterference in the flow of experience (Anderson, 2003, p. 85).

Vipaśśanā is considered a perfect antistress remedy, an effective cognitive technique for the development of self-awareness (Kutz, 1985), and an excellent human potential development method and tool for self-actualization (Chokhani, 1995). *Vipaśśanā* transforms one's approach to life and its vicissitudes including disease, and even death, which one now is able to face with serenity and fortitude. Though *Vipaśśanā* is not advocated for treatment purposes, it may have therapeutic value, and it has been suggested that combining and integrating it with psychotherapy may offer synergistic advantages (Kutz). Studies carried out on the impact of *Vipaśśanā* in jails in India have reported its efficacy as a reformatory measure.

Self-Reliance

The Buddha always stressed the importance of self-discovery, and nonreliance on external authority, even his own. Scientific to the end, his dying words were “Be ye lamps unto yourselves. Rely on yourselves, and do not rely on external help. Look not for assistance to anyone besides yourselves – either now or after I am dead” (Burt, 1955, pp. 49–50).

The Buddha's teachings have been kept alive in true Eastern tradition by several Buddhist Masters.

Jiddu Krishnamurti

Krishnamurti (1895–1986) was probably the most remarkable spiritual scientist in recent

Indian history. Fiercely independent, his approach was in many ways reminiscent of the Buddha's. He was dismissive of authority (including his own) and tradition, and had a completely empirical approach without recourse to theoretical speculation. His "choiceless awareness" sounds similar to Buddhist mindfulness. Like the Buddha, he encouraged people to be their own spiritual guides, and even insisted that he wanted no followers. "To follow another is evil," he said, "it does not matter who it is" (Krishnamurti Information Network).

But whereas the Buddha left a detailed step-by-step methodology, Krishnamurti decried all methods and techniques in the spiritual search. "Truth is a pathless land," he declared, "and you cannot approach it by any path whatsoever" (Krishnamurti Foundation Trust Ltd.). Again, whereas the Buddha created and left behind an organization, the sangha, to carry his message, Krishnamurti was against any organization in the spiritual field, and in his own case, allowed only the most perfunctory of organizations for the limited purpose of preserving an authentic record of his message.

"Discovered" as a young boy by members of the Theosophical Society who were convinced that they had found the modern messiah, Krishnamurti was declared the new World Leader and, by the 1920s, was attracting worldwide attention. Then in 1925 Krishnamurti experienced a mysterious spiritual awakening, and in 1929, in an act of renunciation, he abandoned the Theosophical Society, cut himself off from all organizations, and from that time until his death, traveled round the world speaking as a private person – a secular philosopher with no affiliation to any religion, sect or dogma.

The Core of the Teachings

Krishnamurti taught that man, out of his insecurity, has built within himself images as a fence of security – symbols, ideas, beliefs – religious, political, personal. Man's perception of life is shaped by these concepts established in his mind. His thinking, his relationships and his daily life are dominated by these images. They divide man from man, and are the cause of the

disorder that pervades the consciousness of mankind, and which prevents human beings from properly working together, ultimately resulting in widespread sorrow, conflict, and misery.

The root cause of this delusion is in the fact that we are ignorant of the general nature of our own processes of thought. To be free from this delusion, we must observe the workings of our own minds. Through observation – close attention to and observation of the activity of thought (Krishnamurti called this "meditation") – one discovers the lack of freedom. One does this observation without choice, without criticism, without acceptance or rejection. The very act of this meditation then, in itself, brings order to the activity of thought without the intervention of will, choice, decision, or any other action of the "thinker." The noise and chaos which are the usual background of our consciousness die out, and the mind becomes generally silent. Our day-to-day work is not affected adversely (to the contrary, it becomes more efficient), because thought arises whenever needed for some genuinely valid purpose, and then stops until needed again.

In this silence, said Krishnamurti, something new and creative happens that is of extraordinary significance for all of life. This something cannot be conveyed in words, so he did not attempt to do so. Rather, he asked those who were interested to explore for themselves, through actual attention to the nature of thought.

Man does not have to go to a hermitage or forest to be free. Freedom is found in the "choiceless awareness" of our daily existence and activity. When man becomes aware of the movement of his own thoughts he will see the division between the thinker and thought, the observer and the observed, the experience and the experiencer. He will discover that this division is an illusion. This will lead to pure observation which is insight without any shadow of the past or of time. This timeless insight brings about a deep radical mutation in the mind – and then there is love, compassion and intelligence.

Truth (spiritual truth) cannot be found through any organization, creed, dogma, priest, or ritual, nor through philosophic knowledge, psychological technique, or intellectual analysis. Man has to

find it through the understanding of the contents of his own mind, through observation.

Krishnamurti's teachings are of considerable relevance to mental health. It has been suggested that many of his ideas could be assimilated into modern psychiatric practice and aid toward promotion of mental health (Rao, 1995).

These scientists of the spirit from the land of the *Vedas* have much to offer to the world. Their discoveries may well complement modern scientific advances to make for a better future. While modern science has explored outer space, these are the scientists who have explored inner space. While modern science has perfected some kinds of technology, they have perfected the techniques of self-actualization. Whereas science and modern medicine have gone far ahead in studying and treating disorders of the mind, the spiritual psychology of the East has studied and perfected the further development and evolution of the human mind beyond the so-called normal (Wilber, 1977, 1989). Perhaps a meaningful synthesis of the wisdom of ► [East and West](#) can lead us to the next phase of human evolution, to a better and more loving human existence, what has been aptly termed the "Next Enlightenment" (Anderson, 2003).

Science as a Western Phenomenon

Roshdi Rashed

Philosophers, historians, and sociologists of science all accept as a basic postulate that science is essentially Western. This postulate is still conditioning contemporary scientific ideologies. This article analyzes the characteristics, history, and validity of this doctrine by means of a confrontation with one of the non-Western scientific contributions: science written in Arabic.

Classical science is essentially European, and its origins are directly traceable to Greek philosophy and science; this tenet has survived intact

through numerous conflicts of interpretation over the last two centuries. Almost without exception, the philosophers accepted it. Kant, as well as Comte, the neo-Kantians as well as the neopositivists, Hegel as well as Husserl, the Hegelians and the phenomenologists as well as the Marxists, all acknowledge this postulate as the basis of their interpretations of Classical Modernity. Even until our time, the names of Bacon, Descartes, and Galileo (sometimes omitting the first, and sometimes adding a number of others) are cited as so many markers on the road to a revolutionary return to Greek science and philosophy. This return was understood by all to be both the search for a model and the rediscovery of an ideal. One might impute this unanimity to the philosophers' zeal to pass beyond the immediate data of history, to their wish for radical insight, or to their effort to seize what Husserl describes as "the original phenomenon (*Urphänomen*) which characterizes Europe from the spiritual point of view." One would expect that the position taken by those who have stuck more closely with the facts of the history of science would be quite different, but such is not the case. This same postulate is adopted by the historians of science as a point of departure for their work, and especially for their interpretations. Whether they interpret the advent of classical science as the product of a break with the Middle Ages, whether they defend the thesis of continuity without breaking or cutting, or whether they adopt an eclectic position, the majority of historians agree in accepting this postulate more or less implicitly.

Today, in spite of the works of many scholars on the history of Arabic and Chinese science, in spite of the wide representation of non-Western scientists in *Dictionary of Scientific Biography*, the works of the historians rest on an identical fundamental concept: in its modernity as well as in its historical context, classical science is a work of European man alone. Furthermore, it is essentially the means by which this branch of humanity is defined. Occasionally the existence of a certain practical science in other cultures might be acknowledged; nevertheless, it rests outside history, or is integrated into it only to

the extent of its contributions to the essentially European sciences. These are only technical supplements which do not modify the intellectual configuration or the spirit of the latter in any way. The image given of Arabic science constitutes an excellent illustration of this approach. Essentially it consists of a conservatory of the Greek patrimony, transmitted intact or enriched by technical innovation to the legitimate heirs of ancient science. In all cases, scientific activity outside Europe is badly integrated into the history of the sciences; rather, it is the object of an ethnography of science whose translation into university study is nothing more than Orientalism.

The effects of this doctrine are not limited to the domain of science, its history, and its philosophy. It is at the center of the debate between modernism and tradition. As was the case in eighteenth-century Europe, we find, in certain Mediterranean and Asian countries of today, that science (which is qualified as European) is identified with modernism. Our purpose here is not to redress wrongs, nor to oppose to that science qualified as European an alleged Eastern science. It is simply a matter of understanding the significance of the European determination of the concept of classical science, grasping the reasons for it and measuring its importance.

We shall begin by sketching the history of this view of European science and then estimate its effects. We shall limit ourselves to posing the problem and advancing several hypotheses, and we also add these two restrictions: the only non-European science considered is one which was produced by various cultures, by scholars of different beliefs and religions, all of whom wrote their science principally, if not exclusively, in Arabic. As for the tenets of the history of the sciences, we shall most often cite those of the French historians.

The concept of a European science is already present in the works of the historians and philosophers of the eighteenth century. In the debate of the Ancients and the Moderns, scholars and philosophers referred to science to define modernity where one combines reason and experience. Historical induction intended to give its concrete determinations to this dogmatic debate, so as to

render the superiority of the Moderns indisputable. But the West was already being identified as Europe, and "Oriental wisdom" was already counterpoised against the natural philosophy of the post-Newtonian West, such as we find in Montesquieu's *Persian Letters* (1721).

Classical science is European and Western only to the degree that it represents a stage in the continuous and regular development of humanity. The *Discours Préliminaire* of Abbé Bossut in Diderot's *Encyclopédie Méthodique* offers an illustration of this concept. Dividing the history of the progress of the exact sciences into three periods, this tableau allows conjecture, alleged facts, and facts to intermingle. Its initial postulate is that "...all of the eminent peoples of the ancient world liked and cultivated mathematics. The most distinguished among them are the Chaldeans, the Egyptians, the Chinese, the Indians, the Greeks, the Romans, the Arabs, etc.... in modern times, the western nations of Europe." Classical science is European and Western because, writes Abbé Bossut, "...the progress made by the western nations of Europe in the sciences from the sixteenth century to our times utterly effaces those of other peoples."

The concept of Western science changed in nature and extent at the turn of the nineteenth century. With what Edgar Quinet called the "Oriental Renaissance", the conceptualization was completed in its anthropological dimension in the last century. This Oriental Renaissance ended by discrediting science in the East.

If it is true that the eighteenth-century concept still survived here and there, from the first years of the nineteenth century the materials and ideas of Oriental studies contributed the most to the makeup of the historical themes of the different philosophies. In Germany as well as in France, the philosophers adopted Oriental studies for diverse reasons in accordance with an identical representation: the East and the West do not oppose each other as geographical, but as historical positivities; this opposition is not limited to a period of history, but goes back to the essence of each term. In this regard, *Lessons on the History of Philosophy* and other works of Hegel can be invoked. Also at this time, as is shown by the

French Restoration philosophers, the themes of the “call of the East” and the “return to the Orient” appear, which translate as a reaction against science, and more generally, against Rationalism. But it is with the advent and growth of the German philological school that the notion of science as a Western phenomenon was regarded as having been endowed with the scientific, and no longer purely philosophical, support which had been lacking until then.

This influence also extended into mythological and religious studies. For example, Friedrich von Schlegel distinguishes two classes of language: the flexional Indo-European languages, and others. The former are “noble,” the latter less perfect. Sanskrit, and consequently, German, considered the closest to it, is “...a systematic language and perfect from its conception”; it is “...the language of a people not composed of brutes, but of clear intelligence.” There is nothing surprising in this; with the advent of the German school we are already in the realm of classifying mentalities. From now on everything is in place for effecting the passage from the history of languages to history through languages.

The comparative study of religions and myths is developed around the middle of the century by A. Kuhn and Max Müller in particular. The classification of mentalities is perfected. It is from the basis of these tenets and dating from this period that one of the most important efforts to establish the notion of science as Western and European in an allegedly scientific manner is elaborated. This project achieves its full extent in France in the work of Ernest Renan.

For Renan, civilization is divided between Aryans and Semites; the historian only has to evaluate their contributions in a differential and comparative manner. The notion of race would constitute the foundation of historiography. By race, one meant the whole of the “... aptitudes and instincts which are recognizable solely through linguistics and the history of religions.” In the last analysis, it is for reasons attributable to the Semitic languages rather than the Semites themselves that they did not and could not have either philosophy or science. “The Semitic race,” writes Renan, “is distinguished almost

exclusively by its negative traits: it has neither mythology, epic poetry, science, philosophy, fiction, plastic arts nor civil life.” The Aryans, whatever their origin, define the West and Europe at one and the same time. Arabic science is, “...a reflection of Greece, combined with Persian and Indian influences.”

The historians of science borrowed not only their representation of the Western essence of science from this tradition, but also some of their methods for describing and commenting on the evolution of science. Thus, they applied themselves to discovering the concepts and methods of science and to following their genesis and propagation through philological analyses of the terms and on the basis of the texts at their disposal. Like the historian of myths or of religion, the historian of the sciences must be a philologist as well. In France, the situation is such that philosophers borrow Renan’s interpretation and, often, even his terminology. Even though this brand of anthropology has already been abandoned by historians, they nevertheless preserve and propagate a series of inferences engendered by it. These can be enumerated as follows:

1. Just as science in the East did not leave any consequential traces in Greek science, Arabic science has not left any traces of consequence in classical science. In both cases, the discontinuity was such that the present could no longer recognize itself in its abandoned past.
2. Science subsequent to that of the Greeks is strictly dependent upon it. According to Duhem, “...Arabic science only reproduced the teachings that it received from Greek science.” In a general fashion, Tannery reminds us that the more one examines the Hindu and Arabic scholars, “...the more they appear dependent upon the Greeks... (and)... quite inferior to their predecessors in all respects.”
3. Whereas Western science addresses itself to theoretical fundamentals, Oriental science, even in its Arabic period, is defined essentially by its practical aims.
4. The distinctive mark of Western science is its conformity to rigorous standards; in contrast,

Oriental science in general, and Arabic science in particular, lets itself be carried away by empirical rules and methods of calculation, neglecting to verify the soundness of each step on its path. The case of Diophantus illustrates this idea perfectly: as a mathematician, said Tannery, "...Diophantus is hardly Greek." But when he compares the *Arithmetics* of Diophantus to Arabic algebra, Tannery writes that the latter "...in no way rises above the level achieved by Diophantus."

5. The introduction of experimental norms which, according to historians, totally distinguishes Hellenistic science from classical science, is solely the achievement of Western science.

Thus it is to Western science alone that we owe both the concept and experimentation. We are not going to oppose this ideology to another. We propose simply to confront some of these elements with the facts of the history of science, beginning with algebra and concluding with the crucial problem of the relationships between mathematics and experimentation.

Algebra

As with the other Arabic sciences, algebra had practical aims, a flair for calculation, and an absence of rigorous standards. It is precisely this that allowed Tannery to make his statement. Bourbaki took this as his authorization to exclude the Arabic period when he retraced the evolution of algebra. The historical writings of the modern mathematician Dieudonné are significant; between the Greek prehistory of algebraic geometry and Descartes, he finds only a void, which, far from being frightening, is ideologically reassuring. Some historians cite ► [al-Khwārizmī](#), his definition of algebra and his solution of the quadratic equation, but it is generally to reduce Arabic algebra to its initiator. This restriction misconstrues the history of algebra, which in actuality does not show a simple extension of the work of al-Khwārizmī in the West, but an attempt at theoretical and technical overtaking

of his achievements. Moreover, this overtaking is not the result of a number of individual works, but the outcome of genuine traditions. The first of these traditions had conceived the particular project of arithmetizing the algebra inherited from al-Khwārizmī and his immediate successors. The second one, in order to surmount the obstacle of the solution by radicals of third and fourth degree equations, formulated in its initial stage a geometric theory of equations, subsequently to change viewpoint and study known curves by means of their equations. In other words, this tradition engaged itself explicitly in the first research in algebraic geometry.

As we have said, the first tradition had proposed arithmetizing the inherited algebra. This theoretical program was inaugurated at the end of the tenth century by ► [al-Karajī](#), and is thus summarized by one of his successors, al-Samaw'al (d. 1176): "to operate on unknowns as the arithmeticians work on known quantities."

The execution is organized into two complementary stages. The first is to apply the operations of elementary arithmetic to algebraic expressions systematically; the second is to consider algebraic expressions independently from that which they can represent so as to be able to apply them to operations which, up to that point, had been restricted to numbers. Nevertheless, a program is defined not only by its theoretical aims, but also by the technical difficulties which it must confront and resolve. One of the most important of these was the extension of abstract algebraic calculation. At this stage, the mathematicians of the eleventh and twelfth centuries obtained some results which unjustly are attributed to the mathematicians of the fifteenth and sixteenth centuries. Among these are the extension of the idea of an algebraic power to its inverse after defining the power of zero in a clear fashion, the rule of signs in all its general aspects, the formula of binomials and the tables of coefficients, the algebra of polynomials, and above all, the algorithm of division, and the approximation of whole fractions by elements of the algebra of polynomials.

In a second period, the algebraists intended to apply this same extension of algebraic

calculation to irrational algebraic expressions. Al-Karajī questioned how to operate by means of multiplication, division, addition, subtraction, and extraction of roots on irrational quantities. To answer this question the mathematicians gave, for the first time, an algebraic interpretation of the theory contained in Book X of the *Elements*. This book was regarded by Pappus, as well as by Ibn al-Haytham much later, as a geometry book, because of the traditional fundamental separation between continuous and discontinuous magnitudes. With the school of al-Karajī, a better understanding of the structure of real algebraic numbers is achieved.

In addition, the works of this algebraic tradition opened the route to new research on the theory of numbers and numerical analysis. An examination of numerical analysis, for example, reveals that after renewing algebra through arithmetic, the mathematicians of the eleventh and twelfth centuries also effected a return movement to arithmetic to search for an applied extension of the new algebra. It is true that the arithmeticians who preceded the algebraists of the eleventh and twelfth centuries extracted square and cube roots, and had formulas of approximation for the same powers. But, lacking an abstract algebraic calculation, they could generalize neither their results, their methods, nor their algorithms. With the new algebra, the generalization of algebraic calculation became a constituent of numerical analysis which, until then, had only been a sum of procedures, if not prescriptions. It is in the course of this double movement which is established between algebra and arithmetic that the mathematicians of the eleventh and twelfth centuries achieved results which are still wrongly attributed to the mathematicians of the fifteenth and sixteenth centuries. This is the case with the method attributed to Viète for the resolution of numerical equations, the method ascribed to Ruffini-Horner, the general methods of approximation, in particular that which D. T. Whiteside designates by the name of al-Kāshī-Newton, and finally, the theory of decimal fractions. In addition to methods, which were to be reiterative and capable of leading in a recursive manner to approximations, the mathematicians of the

eleventh and twelfth centuries also formulated new procedures of demonstration such as complete induction.

We have just seen that the concept of polynomials is among those elaborated by the algebraist arithmeticians from the end of the tenth century. This tradition of algebra as the “arithmetic of unknowns”, to use the expression of the time, opened the road toward another algebraic tradition which was initiated by ‘Umar al-Khayyām (eleventh century), and renewed at the end of the twelfth century by ► [Sharaf al-Dīn al-ṭūsī](#). While the former formulated a geometric theory of equations for the first time, the latter left his mark on the beginnings of algebraic geometry.

The immediate predecessors to al-Khayyām, such as ► [al-Bīrūnī](#), ► [al-Māhānī](#), and Abū al-Jūd, had already been able, in contrast to the Alexandrian mathematicians and precisely because of the concept of the polynomial, to treat the problems of solids in terms of third degree equations. But al-Khayyām was the first to address these unpondered questions: can one reduce the problems of straight lines, planes, and solids to equations of a corresponding degree, on the one hand, and on the other, reorder the group of third degree equations to seek, in the absence of a solution by factoring, solutions which can be reached through means of the intersection of auxiliary curves? To answer these questions, al-Khayyām is led to formulate the geometric theory of equations of a third or lesser degree. His successor, al-ṭūsī, did not delay in changing perspective; far from adhering to geometric figures, he thought in terms of functional relations and studied curves by means of equations. Even if al-ṭūsī still solved equations by means of auxiliary curves, in each case the intersection of the curves is demonstrated algebraically by means of their equations. This is important, since the systematic use of these proofs introduces into the practice instruments which were already available to the mathematical analysts of the tenth century: affine transformations, the study of the maxima of algebraic expressions, and with the aid of what will later be regarded as derivatives, the study of the upper bounds and lower bounds

of roots. It is in the course of these studies and in applying these methods that al-ṭūsī grasps the importance of the discriminant of the cubic equation and gives the so-called Cardan formula just as it is found in the *Ars Magna*. Finally, without enlarging any further on the results which were obtained, we can say that both on the level of results as well as that of style, we find al-Khayyām and al-ṭūsī fully in the field allegedly pioneered by Descartes.

If we exclude these traditions and justify this exclusion by invoking the practical and computational aims of the Arab mathematicians and an absence of rigorous standards of proof in their work, we can say that the history of classical algebra is the work of the Renaissance.

Among the mathematical disciplines, algebra is not a unique case. To varying degrees, trigonometry, geometry, and infinitesimal determinations are likewise illustrative of the preceding analysis. In a more general sense, optics, statistics, mathematical geography, and astronomy are also no exception. Recent works in the history of astronomy render Tannery's understanding of the Arab astronomers and the interpretations which he gives of them manifestly outmoded, if not erroneous. But since we assigned ourselves the task of examining the doctrine of the Western nature of classical science, we shall restrict our discussion to an essential component of this doctrine, experimentation.

Experimentation

In fact, is not the cleavage between the two periods of Western science, the Greek period and the Renaissance, often marked by the introduction of experimental norms? Undoubtedly the general agreement of the philosophers, historians, and sociologists of science stops here; the divergences become apparent as soon as they attempt to define the meaning, the implications, and the origins of these experimental norms. The origins are linked in one case to the current of Augustinian-Platonism, in another to the Christian tradition, and particularly to the dogma of

Incarnation, in a third case to the engineers of the Renaissance, in a fourth to the *Novum Organum* of Francis Bacon, and finally, in a fifth, to Gilbert, Harvey, Kepler, and Galileo. Some of these attitudes superimpose upon one another, become entangled or contradictory, but they all converge on one point: the occidental nature of the new norms.

Nevertheless, as early as the nineteenth century, historians and philosophers such as Alexander von Humboldt in Germany and Cournot in France diverge from this predominating position to attribute to the Arab period the origins of experimentation. It is difficult to analyze the origins or the beginnings of experimentation correctly, since no study has been made of the interrelations of the different traditions and the different themes to which the concept of experimentation has been applied. Perhaps it would be in writing such a history, especially a history of the term itself, that one could give an accounting of the multiplicity of uses and ambiguities of the concept. For this analysis two histories are needed: the history of the relationship between art and science and that of the links between mathematics and physics.

With the history of the relationship between science and art, we are in a position to understand when, why, and how it became accepted that knowledge can emanate from demonstrations and from the rules of practice at the same time, and that a body of knowledge possesses the stature of a science while, at the same time, it is conceived in its possibilities of practical realization with an external purpose. The traditional opposition between science and art seems likely to be the work of the intellectual currents of the Arabic period. Certainly one fact is striking: whether we are dealing with Muslim traditionalists, rationalist theologians, scholars of different fields, or even philosophers of the Hellenistic tradition such as ► [al-Kindī](#) or al-Fārābī, all contribute to the weakening of the traditional differentiation between science and art. In other respects, this general trait is at the origin of the opinion of some historians regarding the practical spirit and realistic imagination of the Arab scholars. Knowledge is accepted as scientific

without its conforming either to the Aristotelian or to the Euclidean scheme. This new concept of the stature of science promoted the dignity of scientific understanding of disciplines which traditionally were confined to the domain of art, such as alchemy, medicine, pharmacology, music, or lexicography. Whatever might be the importance of this concept, it could only lead to an extension of empirical research and to a diffuse notion of experimentation. One does witness the multiplication and systematic use of empirical procedures: the classifications of the botanists and the linguists, the control experiments of the doctors and alchemists, and the clinical observations and comparative diagnostics of the physicians. But it was not until new links were established between mathematics and physics that such a diffuse notion of experimentation acquired the dimension that determines it, a regular and systematic component of the proof. Primarily it is in Ibn al-Haytham's work in the field of optics where the emergence of this new dimension can be perceived.

With Ibn al-Haytham the break is established with optics as the geometry of vision or light. Experimentation had indeed become a category of the proof. The successors of Ibn al-Haytham, such as al-Fārisī, adopted experimental norms in their optical research, such as that performed on the rainbow. What did Ibn al-Haytham understand by experimentation? We will find in his work as many meanings of this word and as many functions served by experimentation as there are links between mathematics and physics. A thorough look at his texts indicates that the term and its derivatives belong to several superimposed systems, and are not likely to be discerned through simple philological analysis. But if attention is fixed on the content rather than the lexical form, one can distinguish several types of relationships between mathematics and physics which allow one to spot the corresponding functions of the idea of experimentation. In fact, the links between mathematics and physics are established in several ways; even if they are not specifically treated by Ibn al-Haytham, they underlie his work and are amenable to analysis.

As for the field of geometric optics, which was reformed by Ibn al-Haytham himself, the only link between mathematics and physics is a similarity of structures. Owing to his definition of a light ray, Ibn al-Haytham was able to formulate his theory on the phenomena of propagation, including the important phenomenon of diffusion, so that they relate perfectly to geometry. Then several experiments were devised to assure technical verification of the propositions. Experiments were designed to prove the laws and rules of geometrical optics. The work of Ibn al-Haytham attests to two important facts which are often insufficiently stressed: first of all, some of his experiments were not simply designed to verify qualitative assertions, but also to obtain quantitative results; in the second place, the apparatus devised by Ibn al-Haytham, which was quite varied and complex, is not limited to that of the astronomers.

In physical optics one encounters another type of relationship between mathematics and physics and therefore a second meaning of experimentation. Without opting for an atomistic theory, Ibn al-Haytham states that light, or as he writes, "the smallest of the lights", is a material thing, external to vision, which moves in time, changes its velocity according to its medium, follows the easiest path, and diminishes in its intensity depending on its distance from its source. Mathematics is introduced into physical optics at this stage by means of analogies established between the systems of movement of a heavy body and those of the reflection and refraction of light. This previous mathematical treatment of the concepts of physics permitted them to be transferred to an experimental plane. Although this situation on the experimental level might be somewhat approximate in nature, it nevertheless furnishes a level of existence to ideas which are syntactically structured, but semantically indeterminate, such as Ibn al-Haytham's scheme of the movements of a projectile.

A third type of experimentation, which was not practiced by Ibn al-Haytham himself but was made possible by his own reform and his discoveries in optics, appears at the beginning of the fourteenth century in the work of his successor

al-Fārisī. The links established between mathematics and physics aim to construct a model and to reduce by geometric means the propagation of light in a natural object to its propagation in an artificial object. The problem is to define for propagation, between the natural and the artificial object, some analogical correspondences which were genuinely certain of mathematical status. For example, they built a model of a massive glass sphere filled with water to explain the rainbow. In this case, experimentation serves the function of simulating the physical conditions of a phenomenon that can be studied neither directly nor completely. The three types of experimentation studied all reveal themselves both as a means of verification and as furnishing a plane of material existence to ideas which are syntactically structured. In the three cases, the scientist must realize an object physically in order to handle it conceptually. Thus, in the most elementary example of rectilinear propagation, Ibn al-Haytham does not consider any arbitrarily chosen opening of a black box, but rather specific ones, in accordance with specific geometric relationships, in order to realize as precisely as possible his concept of a ray.

To recapitulate several points:

1. The tenet of the Western nature of classical science which was launched in the eighteenth-century owes to the Orientalism of the nineteenth century the image that we now recognize.
2. On the one hand, the opposition between East and the West underlies the critique of science and rationalism in general; on the other, it excludes the scientific production of the East from the history of science both *de facto* and *de jure*. An absence of rigor is invoked, as well as the computational attributes and the practical aims of science written in Arabic, to justify this effective debarment from the history of science.
3. This tenet reveals a disdain for the data of history as well as a creative capacity for ideological interpretation, which are admitted as

evidence for ideas that raise many more problems than they solve. Thus we have the notion of a Scientific Renaissance, when in several disciplines everything indicates that there was merely a reactivation. These pieces of pseudoevidence quickly become conceptual bases for a philosophy or sociology of science, as well as the departure point for theoretical elaborations in the history of science.

We must ask ourselves if the moment has not arrived to abandon this characterization of classical science and its still lively traces in the writing of history, to restore to the profession of the historian of science the objectivity required of it, to ban the clandestine importation and diffusion of uncontrolled ideologies, to refrain from all reductionist tendencies which favor similarities at the expense of differences, and to be wary of miraculous events in history. The neutrality of the historian is not an *a priori* ethical value; it can only be the product of patient work which will not be duped by the myths which the ► [East and West](#) have engendered. Above all, it is necessary to cast out the periodization everywhere admitted in the history of science. The term used for classical algebra or classical optics, for example, will integrate the works which extended from the tenth to the seventeenth centuries. Consequently, it will realign not only the idea of the classical sciences, but also that of medieval science. The classical sciences will then reveal themselves as the product of the Mediterranean which was the hub of exchanges among all civilizations of the ancient world. Only then will the historian of science be able to enlighten the debate over modernism and tradition.

Science as a Western Phenomenon: Postscript

The 26 years since the publication of the original French edition of the text above has been a very fertile period for the study of the history of Islamic science. Indeed, we have witnessed an

unprecedented rebirth of this discipline. Texts have been written and translated, new collections have appeared, and specialized reviews and journals have been published. These have offered historians the possibility of developing and comparing their research findings with facts. The task remains huge, and we are only at the beginning, but at least this new growth of information puts to rest the argument of ignorance.

With all this new information, one would have expected historians and philosophers to rectify the impressions and ideas they had inherited from the nineteenth century. One would have thought that the doctrine of Western science which we have described and analyzed here would have disappeared along with the props on which that doctrine was based. Indeed we were beginning to see a growing tendency to break with this doctrine and its implications. Then, for reasons which are extraneous to science and its history, images of Islamic society – if not of Islam itself – arose, according to which it was seen as irrational and intolerant and thus a society foreign to science. The aging doctrine was naturally given new life because of these images. How is it possible, under these conditions, to reconcile such an image of Islamic society with scientific results obtained from the heart of that same society? It was enough to back up the preceding doctrine with another, the doctrine of double marginality: with regard to the society which saw the development of science, and with regard to the history of the sciences. Thus, one could still write in 1992, “We must remember that at an advanced level the foreign sciences had never found a stable institutional home in Islam,” or “Greek learning never found a secure institutional home in Islam, as it was eventually to do in the universities of medieval Christendom” (Lindberg, 1992). As for the second marginality, we have already described how it works. Thus, we are back where we started and the doctrine of the Westernness of science is saved. Undoubtedly, these ideological views are beginning to give way, weakened by new research findings. And even if they are still capable of

slowing down the acceptance of facts, it is not widespread, and it certainly will not last much longer.

Science East and West

Dhruv Raina

The social shaping of representations of nonwestern astronomy and mathematics in eighteenth- and nineteenth-century European scholarship has been of recent scholarly interest from the perspective of the politics of knowledge (Charette, 1995; Raina, 1999). My own concern has been to focus upon Indian astronomy and mathematics in the French Enlightenment and post-Enlightenment historiography. In dialogue with Said's *Orientalism*, this exploration has sought to examine whether the history of mathematics (the least likely case) is also inscribed within the frame of European colonial adventure and enterprise, as happened in the arts, literature, and social sciences (Assayag, Lardinois, & Vidal, 1997). In the study of the French Enlightenment I had qualified the Saidian thesis by suggesting that the so-called "European tradition" was fractured along national lines (Raina, 1999). The present project is to focus upon British Indology (Indology refers to the study of India. It is the study of cultural aspects such as religions, philosophies, art, and architecture, as well as spiritual and social aspects.) and its relationship with the corpus of French scholarship that preceded it. More specifically, the article attempts to ascertain when the first texts of Indian astronomy were translated into a European language, and by whom, and it elaborates upon how the Indian tradition of mathematics came to be constructed as one that was devoid of the idea of proof. While this characterization acquired stability in the nineteenth century, the construction itself was prefigured in the eighteenth century. In other words, it is suggested that historians of science mobilized the ideas of proofs or demonstrations as a criterion for demarcating different mathematical traditions.

Edward Said's thesis links the production of knowledge about the Orient with the exercise of colonial power (Said, 1978). Does this thesis

envelope the landscape of European writing on India? The thesis needs qualification from a number of points of view, for the landscape in Said's view is envisioned as monolithic and homogeneous. The eighteenth century has been considered the formative period for the emergence of the discourse on colonialism, but this discourse was not yet "monolithic or univocal." European writing on India comprised a network of "intersecting and contending discourses," and was preoccupied with a wide range of questions on authority (Teltscher, 1995, p. 2). The representations of India in this writing are naturally very "diverse, shifting, historically contingent, complex, and competitive." The texts themselves are shaped often by "national and religious rivalries, domestic concerns," and the cognitive or intellectual cultures of the respective interlocutors (Jami, 1995; Raina, 1999; Teltscher, 1995, p. 2). Critical studies on oriental scholarship have sought to situate these texts in national and religious contexts and to identify the elements they share (Inden, 1990; Županov, 1993). It has been argued that until the eighteenth century it was possible to speak of a European tradition of writing about India that differentiated into several national traditions by the middle of the eighteenth century. The birth of a specifically British tradition is put around 1765 when the East India Company was granted rights to collect land revenues and administer civil justice in Bengal (Teltscher, 1995, p. 3). With the founding of the Asiatic Society British writing on India especially from the 1780s onward was marked by the impulse of British writers to "foreground the textual nature of their activity" (Teltscher, p. 6).

European writing on India following the discovery of the sea route has been categorized into three distinct genres. The first comprises writing relating to travel, trade and the exploits of European powers on Indian soil. This writing was limited to the activities of Europeans in India; wherein an exotic India was presented to the West, and which either projected European superiority or criticized European institutions. But there was little elaboration of the philosophical or religious literature of India or its history (Kejariwal, 1988, p. 14). The missionaries in

India in the seventeenth and eighteenth century provided a second set of accounts. This writing itself is internally differentiated. On the one hand, we have letters recording the progress of missionary activity in India. On the other, Jesuit missionaries resident in India were studying Indian philosophy, religion, and culture. It may even be suggested that they were the first Europeans to be acquainted with Indian languages (Kejariwal, p. 15). And finally, there is the scholarly writing on India. The French missionaries who came to India in the late seventeenth century were the first to have spoken of India's scientific past. French Indology, according to Filliozat, emerged in the early decades of the eighteenth century, when the King's librarian requested Étienne Fourmont, of the Collège Royale, to draw up a list of works of note from India and Indo-China, to be purchased for the King's library. By 1739, a catalogue of Sanskrit works had been prepared, and copies of Vedas, epics, philosophical and linguistic texts, and dictionaries had been procured (Filliozat, 1955, pp. 1–3). Curiously enough there were very few, if any, scientific texts that were included in the cargo to the King's library (Raina, 1999). The first generation of Indianistes was possibly preoccupied with studying the speculations of the Indians, their philosophy, and the “niveau de connaissances scientifiques” (Filliozat, 1954). The Jesuit astronomers were the first to study the Indian astronomical systems that Filliozat considers “the first scientific or even cultural achievements of India studied by Europeans” (Filliozat, 1957). Kejariwal goes so far to suggest that the “history of French Orientalism is also the history of the rediscovery of ancient Indian astronomy in the modern period” (Kejariwal, 1988, p. 17). The latter point needs some nuancing.

In any case, these accounts were constantly contrasting India with Europe, “through explicit analogy or through implied difference.” A fruitful approach into this archive of scientific texts and not just literary or religious texts is to pay attention to moments “which unsettle the confident moments of cultural description,” to trace those “competing and fluctuating logics of similarity and difference,” that characterize the

early discourse of India (Teltscher, 1995, p. 14). In examining these mathematical texts, it is essential to be alert to those moments and descriptions of mathematical results and procedures encountered within Sanskrit texts that were not accompanied by demonstrations or proof or exegesis. Thus the British mathematician and geologist John Playfair in introducing Indian astronomy to an English-speaking audience wrote:

The astronomy of India is confined to one branch of the science. It gives no theory, nor even any description of the celestial phenomena, but satisfies itself with the calculation of certain changes in the heavens... The Brahmin... obtains his result with wonderful certainty and expedition; but having little knowledge of the principles on which his rules are founded, and no anxiety to be better informed, he is perfectly satisfied, if, as it usually happens, the commencement and duration of the eclipse answer, within a few minutes, to his prediction. (Playfair, 1790)

There are three core ideas that are evident in this passage, and that run constantly throughout the construction of Indian astronomy and mathematics. Inasmuch as Indian astronomy is a science it differs from modern astronomy in that it (a) lacks a theoretical basis, (b) does not provide a description of celestial phenomena, and (c) is not methodologically reflective (“little knowledge of the principles on which his rules are founded”). On account of the predictive accuracy of the astronomy it merits being a science, and the Indian astronomers are concerned no more with it than in this instrumental context.

The Origins of British Indology and the History of Indian Mathematics

British studies on Indian astronomy and mathematics may be said to lie at the juncture of two different historiographies: the French historiography of Indian astronomy and British studies on Indian society and culture. Consequently, British historiography of the sciences of India draws upon these sources and develops not unexpectedly in different directions. Without stretching a point too far it could be added that British

Indology on the sciences of India commences with the pioneering work of John Zephaniah Holwell (1711–1798). Holwell came to India as a surgeon's mate in 1732 and was Governor of Bengal for a couple of months in 1760. To historians of science he is best known for his *An Account of the Manner of Inoculating for the Smallpox in the East Indies* (1767). The relevant issue here is not Holwell's article, but the different point of view he adopted for studying the traditions, cultures, and sciences of India. This strayed from the central precepts of Jesuit historiography (Murr, 1986). While insisting as the Jesuits did on the antiquity of the Indian people and their literature, he proposed that this antiquity was not reconcilable with the "Christian view of History" (Holwell, quoted in Kejariwal, 1988, p. 19). Misidentifying his account from earlier European scholarship that he considered "defective, fallacious, and unsatisfactory," Holwell proposed instead a philological approach to the "sublime rational source and foundation" of what to the Western eye appeared preposterous superstition founded on irrationality (Kejariwal, p. 19). It is not germane here to establish whether Holwell could be considered the inaugurator of this approach; but this view was shared by a number of British scholars who founded the Asiatic Society.

One of the earliest British Indologists to speak of the distinctive tradition of Indian algebra was Rueben Burrow. The prior French tradition of the history of science had been preoccupied with the origins of Indian astronomy. Burrow centered the question about the origins of Indian algebra and arithmetic. This will become evident further ahead. That Burrow shared the same viewpoint as Holwell is evident in his "Hints concerning the Observatory at Benaras" (1783):

Notwithstanding the prejudices of the Europeans of the last century in favour of their own abilities, some of the first members of the royal society were sufficiently enlightened to consider the East Indies and China & c, as new worlds of science that remained undiscovered. . . had they not too hastily concluded that to be lost, which nothing but the prejudice of ignorance and obstinacy, had prevented being found, we might at this time (be) in possession of the most finished productions

of Asia as well as Europe; the sciences might, in consequence, have been carried to a much higher degree of perfection with us than they are at present; and the elegance and superiority of the Asiatic models might have prevented the neglect and depravity of geometry, and that inundation of Algebraic barbarism which has ever since the time of Descartes, both vitiated taste, and overrun the publications, of most of the philosophical societies in Europe. (Burrow, 1783, pp. 94–95)

It is evident from the above that beyond the aesthetic of the search for the marvelous, the encounter with other non-European scientific traditions was encouraged by the ideological impulse to advance the frontiers of knowledge. In that sense Burrow's philosophy of science resonated with that of the Enlightenment thinkers. As far as the history of astronomy is concerned, this project was quite consistent with historical astronomy being pursued in China and India since the late seventeenth century (Han, 1995; Raina, 1999). The most striking feature of the above passage is that the Indian tradition for Burrow is not characterized as algebraic or geometric. In fact, at this point the characterization is the very reverse of the late nineteenth-century one. Modern European mathematics since Descartes had been overwhelmed by "algebraic barbarism." An exposure to Asiatic models would then have prevented the neglect of geometry that marked contemporary sciences. The relevant concern here is that "until the end of the eighteenth century the British Indologists still entertained the hope that they would discover Indian geometrical texts that would unveil to them the foundations of an Indian geometrical tradition." Thus Playfair would in 1792 pose six questions to the researchers of the Asiatic Society, the first of which was: "Are any books to be found among the Hindus, which treat professedly of Geometry?" (Playfair, 1792, p. 151). For one it could be said that the question that the geometry of the Hindus could have a different basis from the Greek ones is implied by the "professedly" in the question. That this is what Playfair meant might be inferred from his elaboration upon the question he posed:

I am led to propose this question, by having observed, not only that the whole of the Indian

Astronomy is a system constructed with great geometrical skill, but that the trigonometrical rules given in the translation from the *Surya Siddhānta*, with which Mr. Davis has obliged the world, point out some very curious theorems, which must have been known to the author of that ancient book. (Playfair, 1792, p. 151)

The rule according to which the “trigonometrical canon” of Indian astronomy is constructed according to Playfair, is based on a theorem:

If there be three arches of a circle in arithmetical progression, the sum of the sines of the two extreme arches is to twice the sine of the middle arch as the cosine of common difference of the arches to the radius of the circle. (Playfair, 1799, p. 152)

Although the theorem was not known to Europe before Viète, the method was employed by the Indian astronomers for constructing trigonometrical tables, and was based on a simpler procedure of calculating sines and arches than through the use of methods that were based on extracting square roots (Playfair, 1798, p. 152). The immediate task for Playfair appears to have been to identify those mathematical works where the theorem on which the trigonometrical rule employed in astronomy is first laid out. This brings us back to Burrow’s concern with the origins of Indian mathematics.

Where Are the Geometrical Texts, or Is the Tradition Algebraic?

In the eighteenth century it would be possible to differentiate between the efforts of the British Indologists and that of their French counterparts studying Indian astronomy and mathematics on two counts. Methodologically speaking, while the British Indologists were busy underlining the textual nature of their enterprise, the French astronomers-savants relied a great deal on protoethnographic descriptions of the mathematical and astronomical practices of India. Second, the histories of Indian astronomy of Bailly (1787) and Le Gentil (1781) are preoccupied with astronomical literature and the origins of Indian astronomy.

Even Montucla (1799) relies extensively upon the sources employed by Le Gentil and Bailly and draws inferences concerning Indian mathematics from them. The British Indological tradition on the other hand, engages with specific texts and from the astronomical rules presented there makes a claim that these rules must be based on a mathematical system. They subsequently proceeded to discover mathematical texts. Their focus thus shifts from the origins of astronomy to the origins of Indian mathematics, in particular Indian algebra and arithmetic.

What were the rules encountered and what were the claims made?

Rueben Burrow, a British official in Bengal, was probably amongst the earliest of the British Indologists to engage with the textual tradition of Indian mathematics, although this search was prompted through his exposure to and study of astronomy, including Indian astronomy. This does not mean that these texts did not relate in any way to the histories of Le Gentil and Bailly. Actually, the texts of the former provided an initial viewpoint to interpret the differences between the two traditions. Burrow, like Bailly, entertained a wild hypothesis concerning the origins of the sciences, but this never seemed to have been noticed as much as Bailly’s antediluvian hypothesis. Consequently, for Burrow the study of the procedures employed by Indian astronomers in calculating eclipses would advance the progress of modern astronomy as well: “...and the more so as our methods of calculation are excessively tedious and intricate” (Burrow, 1783, p. 101). The sentiment echoes that of Le Gentil and Bailly, and it is certain that he was acquainted with the work of Le Gentil (Burrow, p. 116), although it is not possible to say the same of Bailly’s *Traité*. This fascination with the computational procedures employed in astronomy led Burrow to infer in 1783 the existence of an advanced algebraic tradition:

It is also generally reported that the Brahmins calculate their eclipses, not by astronomical tables as we do, but by rules. . . If they (the rules) be as exact as ours, . . . it is a proof that they must have carried algebraic computation to a very extraordinary pitch, and have well understood the doctrine of

“continued fractions”, in order to have found those periodical approximations.... (Burrow, 1783, p. 101)

The rules for computing eclipses employed by the Brahmins were not only different, but their complexity varied with the requisite degree of exactness:

...which entirely agrees with the approximation deduced from algebraic formulae and implies an intimate acquaintance with the Newtonian doctrine of series... and therefore it is not impossible for the Brahmins to have understood Algebra better than we do. (Burrow, 1783, p. 101)

This was to become the central point from which in subsequent papers Burrow would build his argument for the existence of an advanced algebra among the Indians. One of the first histories of Indian algebra was authored by Burrow and was entitled “On Early History of Algebra” (Burrow, 1810), and was possibly published posthumously. The paper emphasized the originality and importance of algebra among the Hindus and contained extracts that were translated from the *Bījagaṇita* and ► *Līlāvati*. These extracts were translations into English from Persian translations of the original Sanskrit texts. If we were to go by his own admission in an earlier paper (Burrow, 1790), these extracts were translated in 1784, but he deferred publishing them until a full text was obtained. But he prizes the moment “when no European but myself... even suspected that the Hindoos had any algebra” (Burrow, p. 115). The rationale provided for the existence of treatises on algebra in India in this paper is based on the knowledge of the binomial theorem among the Indians and is the same as that suggested in the earlier paper. Many of the approximations used in astronomy were “deduced from infinite series; or at least have the appearance of it” (Burrow, p. 115). These included finding the sine from the arc and determining the angles of a right-angled triangle given the hypotenuse and sides without recourse to a table of sines, etc.

The urgency of the moment was then to discover those texts before they perished. Burrow

thus emphasized the need for the collection of available astronomical and mathematical texts that until then had not been the focus of attention of the French Académiciens. The idea that the existing tradition was probably algebraic was being insinuated:

That many of their books are depraved and lost is evident, because there is now not a single book of geometrical elements to be met with; and yet that they had elements not long ago, and apparently more extensive than those of Euclid is obvious from some of their works of no great antiquity. (Burrow, 1790, p. 115)

And while Burrow promised to publish translations of *Līlāvati* and the *Bījagaṇita*, the promise was not fulfilled possibly during his life. Inspired by Burrow’s research, Colebrooke embarked on a study of Sanskrit in order to probe some of the issues raised more deeply.

But the just-mentioned paper by Burrow contains a very brief demonstration of the knowledge of the binomial theorem in the Indian tradition, which unlike Newton’s understanding was limited to whole numbers alone. Burrow first offers a translation from Persian of the problem:

A Raja’s palace had eight doors, now these doors may either be opened by one at a time, or by two at a time, and by three at a time; and so on through the whole, until at last all are opened together: it is required to tell the number of times that this can be done. (Burrow, 1790, p. 118)

Setting out the procedure for resolving it follows the statement of the problem. Write down the number of doors by decreasing from eight to unity. Just under these numbers write down the numbers in the reverse order.

- *Step 1.* The number of times the door can be opened one at a time is obtained by dividing the first number 8, by the number under it, the quotient being 8.
- *Step 2.* To obtain the number of times that two different doors may be opened, multiply the quotient 8 by the next number 7, and divide the product by 2 beneath it, the result being 28.

- *Step 3.* To obtain the number of times three different doors may be opened, multiply 28 by the next number 6, and divide the product by 3, and the quotient is 56.

8	7	6	5	4	3	2	1
1	2	3	4	5	6	7	8

And so on.

“The sum of all the different times is 255” (Burrow, 1790, p. 119). This setting out of the procedure, Burrow calls a “demonstration” and insists that it should be “evident” to mathematicians when inspecting the coefficients of a general equation. So to Burrow goes the credit for providing the first glimpses into the Indian algebraic tradition.

It was left to Samuel Davis to publish the first full-fledged translation and analysis of an Indian scientific work from the Sanskrit into a European language. This was a translation of the *Sūryasiddhānta* (Davis, 1789). This translation was based on the reading of an original version of the text procured by Sir Robert Chambers in 1788. Davis encountered a number of obscure technical terms and had to rely upon a *teeka* or commentary procured by Jonathan Duncan (Davis). In fact, if you examine the structure of Davis’ paper, it appears as a *teeka* on the *Sūryasiddhānta*, with passages translated from the text and Davis’ explanation intercalated between the translated passages. Most British Indologists who worked on Indian astronomy toward the last decades of the eighteenth century were familiar with two canonical European accounts, that of Bailly and Le Gentil.

Without referring to either, Davis begins by contesting the portrait of Indian astronomy and astronomers projected by Le Gentil and Bailly. (More than Bailly and Le Gentil, Davis was refuting Sonnerat’s constructions of Indian astronomy: “my present intention, which is to give a general account only of the method by which the Hindus compute eclipses, and thereby to show, that a late French author was too hasty in asserting generally that they determine by set

forms, couched in enigmatical verses & C.’ So far are they from deserving the reproach of ignorance, which Mons. Sonnerat has implied, that on inquiry, I believe the Hindu science of astronomy will be found as well known now as it ever was among them, although perhaps, not so generally, by reason of the little encouragement men of science at present meet with. . .” (Davis, 1789, p. 177). Evidently, Sonnerat, unlike Davis, could not enter the world of the Hindu astronomers on account of his inability to abandon a hermeneutic of suspicion.) without naming either of them. The first idea that he rejected was that this astronomical tradition was disfigured over the years by idolatry and that the gems of Indian astronomy had been irretrievably lost over the centuries, in the absence of a textual tradition. The second idea was that the Brahmins had shrouded their astronomy in mystery such that it was impossible to arrive at a cogent account of it. Further, they loathed sharing their ideas with others. Davis set out to show that:

... numerous treatises in Sanskrit on astronomy are procurable, and that the Brahmins are willing to explain them. . . I can further venture to declare that, from the experience I have had, that Sanskrit books in the science are more easily translated than almost any others, when once the technical terms are understood: the subject of them *admitting neither of metaphysical reasoning nor of metaphor*, but being delivered in plain terms *and generally illustrated with examples in practice*. (Davis, 1790, p. 175) (emphasis added)

The British Indologists were departing from the reading of Académiciens grounded in Jesuit protoethnography, by textually locating their work. This textual grounding would revise the portrait of the French savants (Table 1). A hundred years later in a review of the history of the history of Indian astronomy Burgess was to write: “Mr. Davis’ paper, however, was the first analysis of an original Hindu astronomical treatise, and was a model of what such an essay ought to be” (Burgess, 1893, pp. 730–731). It appears then, as has been argued elsewhere, that the French savants in India were unable to establish trust

Science East and West, Table 1 French savants and British Indologists

with their Indian interlocutors, in total contrast to the first generation of British Indologists such as William Jones (Raj, 2001). Two papers of William Jones followed closely on the heels of Davis' papers and a cursory glance at them reveals that they mutually respected and supported each other's enterprise. And yet they both were in agreement with Bailly's thesis of the

independent origins of the Indian zodiac, differing very strongly with Montucla on this count:

I engage to support an opinion (which the learned and industrious M. Montucla seems to treat with extreme contempt) that the Indian division of the zodiac was not borrowed from the Greeks or Arabs, but having been known in this country from time immemorial and being the same in part with other nations of the old Hindu race. . . . (Jones, 1790)

But then they were also gradually transforming and refining the portrait Bailly had left behind. Thus Jones recognized that in Davis' translation resided the hope that it would "convince M. Bailly that it is very possible for an European to translate and explain the Surya Siddhānta" (Jones, 1790a).

John Playfair's Program and Colebrooke's Recovery of Indian Algebraic Texts

As far as the history of Indian astronomy and mathematics is concerned I have tried to argue that the French Jesuits of the seventeenth and eighteenth century are the inaugurators of a tradition, which was to inspire the histories of Le Gentil and Jean-Sylvain Bailly (Raina, 1999). As has been argued elsewhere, it was Bailly's history that inspired the work of the British mathematician John Playfair and provided a stimulus to subsequent generations of British Indologists writing on Indian mathematics; although they were to disagree with the details of Bailly's *Histoire*, adding some nuance here and digressing from it in another context (Raina, 2001). The antediluvian hypothesis proposed by Bailly was the source of both fascination and controversy, and was the outcome of his attempt to juxtapose observations of ancient Indian astronomy with astronomical theory of his day; from which he went on to draw the inference that ancient Indian astronomy was the source of Greek astronomy (Bailly, 1775). However, this reading was located within Jesuit historiography that sought to accommodate Indian history within the Christian conception of history (Raina, 2003).

Bailly's work was introduced to English-speaking readers through an article authored by the mathematician and geologist John Playfair (1748–1819), entitled "Remarks on the Astronomy of the Brahmins" published in the *Transactions of the Royal Society of Edinburgh* in 1789 (Playfair, 1790). The article draws extensively upon the *Mémoires* of Le Gentil (1785)

published by the Académie des Sciences, Paris and Bailly's *Astronomie Indienne* (Bailly, 1785). This article of Playfair's was of prime importance for Indologists working on the history of Indian astronomy for the next four decades, despite the fact that it was inspired by the work of such "unvulgariser."

Just in and around the time Bailly's *Traité* appeared, the important tradition of British Indology was beginning to crystallize. Marsden and Bentley were the first to contest Bailly's assumptions and calculations. This opened the floodgates of criticism in France. Playfair jumped into the controversy attacking Bailly's critics for their amateurism and for daring to question Bailly's superior abilities. One of the early papers of the legendary William Jones was dedicated to defending Bailly's thesis concerning the origins of the Hindu zodiac. Playfair's central contribution resided in reappropriating Bailly's *Traité* in the light of the contributions of Davis and Burrow and proposing a set of tasks that could well be considered a research program for the Asiatic Society. These included (a) to search for and publish works on Hindu geometry; (b) to procure any books on arithmetic and going by Burrow's article on the binomial theorem amongst the Indians to ascertain those arithmetical concerns whose trace is not to be found among the Greeks; (c) to complete the translation of the *Sūryasiddhānta* as initiated by Samuel Davis; (d) to compile a catalogue raisonné, with a scholarly account of books on Indian astronomy; (e) to examine the heavens with a Hindu astronomer in order to determine their stars and constellations; and (f) to obtain descriptions and drawings of astronomical buildings and instruments found in India (Playfair, 1792, pp. 152–155).

Bailly had stirred a hornet's nest in his time by suggesting that the origins of astronomy were in India, albeit this astronomy was inherited by the Indians from an even more ancient people. Burrow's paper did the same with the origins of algebra. It is at this time difficult to separate the discussion on the history of astronomy from the history of algebra; for both the Académiciens and

the Indologists often turn to the history of astronomy to evoke computational procedures that were analyzed mathematically. This program of the recovery of the mathematical literature from the astronomical literature was taken up by Colebrooke, who may be seen as providing translations from the Sanskrit into English of the first texts supposedly dedicated solely to algebra and arithmetic. I say supposedly because portions of some of the texts that Colebrooke's discovers for the English-speaking world were essentially the mathematical sections of larger astronomical canons of the Indian tradition.

A brief recapitulation is required before we proceed to the translations of Colebrooke, for his work certainly marks a departure in the study of the history of Indian mathematics. The objective of this study thus far has been to examine the textual legacy that leads up to the translations of Colebrooke. Stated briefly, two main historiographic currents in the eighteenth century oriented the study of the history of the mathematics and astronomy of India. The first approach was that pursued by the Jesuit savants in India, who were observing the astronomical and computational procedures circulating among Indian astronomers. Their audience did not merely comprise the devout back in France, but the Académiciens and astronomers, two of whom transcribed these protoethnographic accounts into a history of Indian astronomy. Administrator-scholars, who studied texts, collated fragments of texts, and published translations with critical editions and commentaries, while indebted to the first, pursued another approach. In the late eighteenth century, Sanskrit commentaries and canonized astronomical or mathematical works were considered the key to obscure technical terms and texts. What needs to be examined is whether by the late nineteenth century, commentaries shared the same destiny as some of the Vedic texts. For it has been pointed out that by the second half of the nineteenth century some Sanskritists belittled, marginalized, and removed "explicit references to the intermediary process of transmission and exegesis of texts without which they would not have had access to them" (Vidal, 1997, p. 25). The status of proofs in the

Indian tradition is related to how these commentaries on mathematical texts were read.

	Trope of forgetting	Trope of disfigurement	Historiography
Jesuit savants	The Brahmins had forgotten the original true Noahic religion from which they had descended and fallen into idolatry	The religion of the Brahmins had been disfigured over the centuries as they had tumbled into idolatry and superstition	Jesuit historiography of India
Astronomer savants of the French enlightenment	The Brahmins had forgotten the intelligence of the astronomical methods that had been their legacy from an ancient people	The Brahmins had disfigured the core of an ancient science that they had inherited from an ancient people	Enlightenment historiography of astronomy

Taken from Raina (2003)

The point needs some reaffirmation, since both Colebrooke and Davis who worked with commentaries of canonized astronomical and mathematical texts, respectively, do mention the existence of demonstrations and rules in the texts they discuss. In Colebrooke's introduction to his *Algebra with Arithmetic and Mensuration, from the Sanscrit of Brahme Gupta and Bhascara*, there are four terms of concern to us here, namely, demonstration, rule, proof, and analysis that come up often, but it is only the last of these that Colebrooke clarifies. Noted by its absence in the title is the term "geometry," as a systematized science; on the contrary, the translation does allude to mensuration as discussed in the books he translates. The crucial problematic for Colebrooke was, as with Burrow before him, to determine the origins of Indian algebra. Inspired, as it were, by the textual exemplars of Davis and Burrow, and guided by the research program John Playfair had drawn up for the researchers of the Asiatic Society, Colebrooke highlighted the pathway to his own work:

In the history of mathematical science, it has long been a question to whom the invention of algebraic analysis is due, among what people, in what region

was it devised, by whom was it cultivated and promoted, or by whose labours was it reduced *to form and system*. (Colebrooke, 1817, p. 121) (emphasis added)

The subsequent narrative focuses upon establishing that “the imperfect algebra of the Greeks,” that had through the efforts of Diophantus advanced no further than solving equations with one unknown, was transmitted to India. The Indian algebraists, through their ingenuity, advanced this “slender idea” to the state of a “well-arranged science” (Colebrooke, 1817, pp. 145–146). In his reading, Colebrooke shares a fundamental historiographic principle, disputed by current scholarship, with Burrow, one that enjoyed currency among historians of mathematics into the twentieth century. In this historiographic frame,

...the Arabs themselves scarcely pretend to the discovery of Algebra. *They were not in general inventors but scholars*, during the short period of their successful culture of the sciences. (Colebrooke, 1817, p. 121) (emphasis added)

The science of “algebraic analysis,” a term Colebrooke would later expand upon, existed in India before the Arabs transmitted it to modern Europe (Colebrooke, 1817, p. 121). The evidence for these claims resided in the translations of the *Bījagaṇita* and ► *Līlāvati* of Bhāskarācārya, (I have given here the contemporary English spellings of the names of Sanskrit books and scholars. Colebrooke himself spelled the *Bījagaṇita* as *Vija-Gaṇita* and Bhāskarācārya as Bhascara Acharya.) as well as Brahmagupta’s (Colebrooke: “Brahmegupta”) *Gaṇitadhyāya* and *Kuṭṭakadhyāya* (Colebrooke: “Cuttacadyaya”), the last two as their name suggests were the mathematical sections of Brahmagupta’s *Brāhmasphuṭasiddhānta*. Without focusing too much on the antiquity of these texts, Colebrooke saw his oeuvre as disclosing that the

...*modes of analysis*, and in particular, *general methods for the solution of indeterminate problems* both of the first and second degrees, are taught in the *Vija-Gaṇita*, and those for the first degree repeated in the *Līlāvati*, which were unknown to the mathematicians of the west until invented anew

in the last two centuries by algebraists of France and England. (Colebrooke, 1817, p. 124) (emphasis added)

The terrain of historical studies on Indian mathematics was being transformed into a polemical one, with Colebrooke surreptitiously introducing categories that the French Indologists had denied the Indian tradition: typically for the first time he speaks of “modes of analysis,” or the “general methods for the solution of indeterminate problems.” The historians of astronomy had previously advanced the idea that the Indians had no idea of the generalizability of the methods they employed. In the absence of such generalizability, how could it have been possible to extend the idea of generalized methods dedicated to solving classes of problems in order to extract the different “modes of analysis”? The intention here is not to paint Colebrooke’s construction as the diametrical opposite of that of the French historians of science that provided a context to his effort. On the contrary, Colebrooke’s project is naturally marked by a deep ambivalence. The ambivalence arises from the fact that he attempted to draw the characterization of Indian mathematics away from the binary typologies of the history of science that were already set in place. The lack of mathematical authority amongst the network of the British Indologists served as major handicap and deterred his ability to create a new vocabulary. This also explains why John Playfair was so important to the Indological enterprise. He was a mathematician of repute who conferred the Indological accounts with authority.

However, Colebrooke begins by pointing out that ► *Āryabhaṭa* was the first of the Indian authors known to have treated of algebra. Possibly a contemporary of Diophantus, the issue was important for drawing an arrow of transmission from Alexandria to India or vice versa. Colebrooke leaves the issue of the invention of algebra open by suggesting that it was Āryabhaṭa who developed it to the high level (The high level of attainment was ascribed to the ability of the Indian algebraists to solve equations involving several unknowns and of possessing a general

method of solving indeterminate equations of the first degree (Colebrooke, 1817, p. 130).) that it attained in India; this science he called an “analysis” (Colebrooke, p. 130). It is here for the first time that a portion of the Indian mathematical tradition is referred to as analysis, and it is important to get to the sense in which he employs the term. Thus it is noticed that the use of a notation and algorithms is crucial to this algebraic practice. Colebrooke then proceeds to elaborate upon the idea and takes note of the procedures not merely for denoting positive or negative quantities or the unknowns but of manipulating the symbols employed (Colebrooke, pp. 131–132). An important feature of this algebra is that all the terms of an equation do not have to be set up as positive quantities; there is no rule requiring that all the negative quantities be restored to the positive state. The procedure is to operate an equal subtraction “. . . (*samasodhana*) for the difference of like terms.” This operation is compared with the *muqabalah* employed by the Arab algebraists (Colebrooke, p. 135). The presence of this “analytic art” among the Indians was apparent from the canvas of their mathematics.

This included the arithmetic of surd roots, the cognizance that when a finite quantity was divided by zero the quotient was infinite, an acquaintance with the procedure for solving second-degree equations and “touching upon” higher orders, solving some of these equations by reducing them to the quadratic form, of possessing a general solution of indeterminate equations in the first degree. And finally, Colebrooke finds in the *Brāhmasphuṭasiddhānta* §18:29–49; and *Bījagaṇita*: §75–99; a method for obtaining a “multitude” of solutions to second-degree equations starting from a single solution that is plugged in. It was left to Lagrange to show that problems of this class would have solutions that are whole numbers (Colebrooke, 1817, pp. 135–136). The analytic art of the Indians or algebraic analysis is then for Colebrooke: “. . . calculation attended with the manifestation of its principles.” This is manifest in the Indian mathematical texts being discussed since they intimate to the reader a “method aided

by devices, among which symbols and literal signs are conspicuous” (Colebrooke, p. 141). In this sense Indian algebra bears an affinity with D’Alembert’s conception of analysis as the “method of resolving mathematical problems by reducing them to equations” (Colebrooke, p. 141). Delambre and Biot would subject these views of Colebrooke to trenchant criticism, but that is another subject (Raina, 1999). The issue at stake here is that Colebrooke had insinuated the idea that Indian mathematics was not lacking in methodological reflection or generality, a feature that had hitherto been denied.

Did this algebraic analysis provide for demonstrations or proofs of its rules or procedures? Citing specific sutras from the *Brāhmasphuṭasiddhānta*, the *Bījagaṇita* and the ► *Līlāvātī*, Colebrooke moves to a characterization of Indian algebra, just as Diophantus is evoked to characterize early Greek algebra. Thus, we are informed that these Indian algebraists applied algebraic methods both in astronomy and geometry, and in turn, geometric methods were applied to “the demonstration of algebraic rules.” Obviously, Colebrooke was construing the visual demonstrative procedures employed by Bhāskara as exemplifying geometrical demonstration. Further, he goes on to state that:

In short, they cultivated Algebra much more, and with greater success than geometry; as is evident in the comparatively low state of their knowledge in the one, and the high pitch of their attainments in the other. (Colebrooke, 1817, p. 136)

This passage came to be quoted so often in subsequent histories of science, and in the writings of mathematicians (The nineteenth-century British mathematician Augustus De Morgan, a self-proclaimed aficionado of Indian mathematics, wrote a preface to the book of an Indian mathematician punctuated with aperçus from Colebrooke’s introduction. The introduction in fact provides him the ground to legitimate the work of the Indian mathematician for a British readership (Raina & Habib, 1992).) as evidence of the algebraic nature of Indian mathematics. The power of its imagery resides in its ability to draw the boundary between different civilizational styles of mathematics. In this contrast

between Western and Indian mathematics it could be suggested that Colebrooke's qualification concerning the "comparatively low" state of one and "high pitch" of the other was lost sight of, and the contrast between the two traditions came to be subsequently accentuated.

This leads me to conjecture that Colebrooke's translation is a watershed in the occidental understanding of the history of Indian mathematics on a second count as well; this is that it inadvertently certified the boundary line drawn between Indian algebra and Greek geometry. This was not Colebrooke's intention at all, but a consequence of the comparative method he had adopted. Colebrooke's particular comparative method consisted in displaying where India's specific contributions to mathematics resided, and he always contrasted these contributions with the Greek and Arab traditions of mathematics (Going by his text alone, he appears to have been totally oblivious of Chinese mathematics.). This attempt to accentuate the contrast certainly revealed the differences, but with the loss of the context of the contrast, it was first transformed into a caricature and then stabilized as a characterization. The boundary lines had however been marked out before Colebrooke's time (This passage reminds me of the simplistic manner in which Marx's "religion is the opium of the masses" is read out of context.).

Thus there are four specific areas in which "Hindu Algebra appears particularly distinguished from the Greek" (Colebrooke, 1817, p. 137). Some of these have been mentioned above. The additional one that has not been mentioned concerns the application of algebra to "astronomical investigation and geometrical demonstration." In the process the Indian algebraists, Colebrooke suggests developed portions of mathematics that were reinvented recently. This last statement of his prompted a very severe reaction. He then takes up three instances, which he considers "anticipations of modern discoveries" from the texts he discusses and lays out their procedures of demonstration. There is nothing in the subsequent portion of the introduction to

suggest that he did not consider these as demonstrations.

On reading of the early responses from a French savant to the work of Colebrooke, it is possible to discern that Delambre for one uses a very fine comb in rebutting several of the points taken up by Colebrooke. While Colebrooke himself does not draw a very fine distinction between the use of the term "proof" and "demonstration" in his reading, he does distinguish between algebra and analysis, and as mentioned earlier, he specifies wherein the Indian tradition could be characterized as an algebraic analysis. A study of the reception of Colebrooke's translations of the works on Indian arithmetic and algebra is a matter for a separate study. The curious question to be examined by such a study is that despite its canonical status in Western scholarship on the history of Indian mathematics and algebra, neither Colebrooke nor Davis ever insinuated that it was a tradition devoid of proof or demonstration. And yet, as the historiography of nineteenth-century Oriental mathematics evolved, a theory of the absence of proof would become one of its salient elements. One of the factors responsible for the strong criticism of Colebrooke's work at the time was that it might have been provoked by Colebrooke's method of taking up those demonstrations from Indian mathematics for which equivalents existed in eighteenth-century European mathematics. This would have vitiated both the claims of novelty and originality, both very important features of the new sciences. Second, until the end of the eighteenth century these Indologists still believed that they could discover the origins of an Indian geometry, and the later work of the French Indologist G. Thibaut may be seen to be in continuity with this tradition. But by the end of the nineteenth century the binary typologies of the history of mathematics, that portrayed the West as geometric and the East as algebraic, were well in place in the standard picture.

Science in China

Ho Peng Yoke

Scholars in the past found it difficult to focus their attention on Chinese science because in traditional China knowledge did not come under the same groupings as in the West. For example the Chinese pharmacopoeias included knowledge on natural history; the official dynastic histories, some Daoist writings, and the works of some great poets contain information on astronomy and alchemy, and compendia on military science mention meteorology and firearms together with magic and divination. It is true that there are some Chinese monographs on science and technology, such as the *Tiangong kaiwu* (Exploitations of the Work of Nature) and the *Jiuzhang suanshu* (Mathematical Manual of the Nine Sections). Nevertheless knowledge of traditional Chinese science exists mainly in the official dynastic histories, the compendia (*leishu*), the gazetteers, religious works like the *Daozang* (Daoist Tripitaka), the numerous book collections (*congshu*), and the general literature.

In sixteenth-century Europe, Francis Bacon (1561–1626), Jean Fernal (1497–1558), and Jerome Cardano (1501–1576) all made reference to three great inventions, namely the compass, the art of printing, and ► [gunpowder](#). In the minds of many there was only some vague connection between China and these three inventions. Indeed, prior to the middle of the twentieth century the history of Chinese science received little attention both from inside and

outside China. It gained recognition in the middle of the twentieth century when Joseph Needham launched his monumental work, *Science and Civilisation in China*. Needham did not pioneer the study of the history of Chinese science. Sinologists and scientists before him had written on acoustics, alchemy, architecture, astronomy, gunpowder, hydraulics, mathematics, and medicine in traditional China. However, Needham demonstrated the originality of many Chinese discoveries and inventions, including the “three great inventions” of Renaissance Europe, and made Chinese science a new discipline of study. Modern scholarship and recent archaeological discoveries have increased our understanding of Chinese science and helped in the reappraisal of some old interpretations.

Excavations carried out first at Anyang between 1928 and 1937 and again after 1950, followed by those done at Zhengzhou in Henan province, substantiated the existence of the Shang dynasty (sixteenth–eleventh centuries BCE) and brought to light many bronze artifacts, foundry sites, and proto-porcelain wares. At the ruins in Anyang the remains of the capital of the last Shang kings were found. This later period of the Shang dynasty is known as Yin (fourteenth–eleventh centuries BCE). Besides bronze artifacts, archaeologists uncovered gold, jade, pottery, and shell objects, wooden artifacts with traces of lacquer, traces of silk fabric, and even a chariot. The most important find, however, was the oracle bones, which were carapaces of a species of tortoise or shoulder blades of buffaloes that bear inscriptions written by the people of Yin for divination purposes. They contain records of eclipses and novae, as well as names of stars and asterisms. They also show that the Yin people were already using a lunisolar calendar with 12 moons or lunar months in 1 year. Each month consisted of either 29 or 30 days each, and every 2 or 3 years there was one extra month, known as the intercalary month, added to the year. The numerals in the oracle bones were the earliest known Chinese numerals until the discovery of the inscriptions on the pottery at the ruins of Banpo, which dated back to about the year 3000 BCE. From the oracle bone numerals

we know that the Yin people were already using a decimal system. We also find that the Yin people already had some knowledge of irrigation, agriculture, sericulture, and wine-making. For example, for tooth decay they used a character that included the character for “worms,” suggesting that they had made an effort to attribute the problem to a cause. Chinese archaeologists have been quite active in recent years trying to re-establish the Xia dynasty. According to their tradition this dynasty existed for four centuries immediately before Shang, which itself lasted six centuries. Erlitou in Henan province, where bronze vessels dating back to the year 1700 BCE were recovered in 1971, is one of the more promising sites where they hope to discover epigraphical evidence to confirm the existence of that ancient dynasty.

Bronze vessels and pottery are some of the works of art characteristic of the Chinese. Shang bronzes show that the technique of bronze casting had already reached an advanced level. It was also in Shang China that the earliest proto-porcelain ware was discovered. It took the form of a wine container (*cun*), made of kaolin clay, with a yellowish green glaze on the surface about the mouth and a translucent deep green glaze on the inner and outer surfaces. The Western Zhou period (eleventh century – 771 BCE) produced beautiful bronze vessels with inscriptions and proto-porcelain wares, some of which can be seen in many museums today.

In the Spring-and-Autumn period (722–481 BCE) two early texts, which Confucius (551–479 BCE) himself referred to, namely the *Shujing* (Book of Documents) and the *Shijing* (Book of Odes), were written. Both contain astronomical material from about the tenth to the fifth century BCE. The earliest sighting of Halley’s comet in the year 613 BCE is recorded in the *Chunqiu* (Spring-and-Autumn Annals), which also contains references to solar and lunar eclipses, meteor streams, and other comets. The *Zhouli* (Records on the Rites of Zhou) informs us that the Zhou kings employed star clerks to observe astronomical and meteorological phenomena and to make astrological prognostications therefrom. The earliest star catalog is said to have been made by a court astronomer

Wu Xian, of whom little is known. Two other catalogs were produced by ► [Gan De](#) and Shi Shen between 370 BCE and 270 BCE. The three original catalogs have long been lost. Some fragments claimed to be from the originals are quoted in many old astronomical writings. In the early fourth century Chen Zhuo (fl. ca. 310) constructed a star map supposedly based on such information.

Two weapons with iron plates taken from meteorite sources and dating back to the Western Zhou period were discovered in 1949. In 1976 a steel weapon of the sixth century BCE was excavated in Changsha, Hunan province, showing that by then China had already entered the Iron Age. Subsequently more iron artifacts of the fifth century BCE were found in Jiangsu and Henan provinces. It is interesting that although Europe knew about iron earlier, the Chinese came to know about the making of cast iron not later than the fifth century BCE, soon after iron was known to them. Another interesting technology developed by the Chinese of about that period is the breast-strap harness seen on the horses among the terra cotta warriors guarding the tomb of Qin Shihuangdi in Xian. Showing good understanding of the horse, this method was far superior to the throat-and-girth harness of the Roman chariot adopted in Europe in the early days. Some time between the years 600 and 1,000 the breast-strap technique went to Europe and evolved into the modern harness.

Between the sixth and the fourth centuries BCE the “Hundred Schools of Philosophical Teachings” flourished in China. Some of these schools played an important role in the development of science and technology in China. The philosopher Mozi (b. ca. 479 BCE) is remembered for his techniques of defense and for his knowledge of mechanics and optics embodied in his *Mojing* (The Canon of Mozi). Confucius is said to have edited the *Yijing* (Book of Changes), which contains one of the most subtle and influential methods of Chinese divination. In the past, especially in China, it was difficult to draw a sharp line of demarcation between science and divination. These two subjects were included within the term *shuxue* (mathematics).

The writings of the Daoist philosophers and the Naturalists exerted a great influence on early Chinese science, and indeed they provided a set of natural laws that was supposed to be “universal”, even more so than what modern scientists believe. Indeed the attempt to be too universal made it difficult for science in traditional China to separate itself from philosophy and to develop into modern science. The greatest name among the Naturalists was ► [Zou Yan](#) (fl. ca. 300 BCE) who lived in the eastern seaboard state of Qi (in modern Hebei province). He was the greatest exponent of the yin and yang theory and that of the *wuxing* in ancient China.

Traditional Chinese science was based on the philosophy of Harmony of Nature, in which heaven (*tian*), earth (*di*), and human beings (*ren*) were all mutually related. Attempts were made to develop a philosophy to explain everything – from astronomy to astrology, from mathematics to fortune-telling, from alchemy to magic, from philosophy to ethics, from politics to fine arts, and from medicine to music – in a common concept based on *qi*. The word *qi* has a wide range of meanings, which cannot be adequately covered by a single term in translation. Its modern meaning includes “air”, “gas”, “vapor”, “steam”, “weather”, “trend”, “demeanor”, “manner”, “temper”, and a sort of life-giving force, reminding us of the Greek concepts of *pneuma* and *psyche*, the Hindu idea of *prāṇa*, and what modern scientists call “matter-energy”.

From *qi* the two opposite and yet complementary cosmological forces yin and yang and the five *xings* were derived. Yin conveys the idea of darkness, the shady part of a mountain, coldness, cloudiness, rain, anything that is feminine, and so on. Yang, on the other hand, refers to brightness, the sunny side of a mountain, warmth, clear sky, sunshine, anything that is masculine, etc. The term *wuxing* was generally translated as “Five Elements”. This gave rise to some confusion. When the Jesuits rendered the Four Elements of the ancient Greeks into Chinese they used the term *siyuan*, (four *yuan*s), but when they translated the Chinese term *wuxing* they called it Five Elements. Unlike the Greek Elements (earth, air, fire, and water), the Chinese *xing*’s were not

stationary but were in a state of constant motion rather than rest. They are Fire, Water, Wood, Metal, and Earth. There is an order of production or generation in which Fire produces Earth, Earth produces Metal, Metal produces Water, Water produces Wood, and Wood produces Fire. Then there is an order of conquest or destruction in which Fire conquers Metal, Metal conquers Wood, Wood conquers Earth, Earth conquers Water, and Water conquers Fire. In Chinese medicine for example, the ► [Huangdi neijing](#) divides different parts of the body into yin and yang and associates them with the five *xings*. For example, the heart, the small intestines and the tongue are associated with Fire, the kidneys and the ears with Water, the gall-bladder and the eyes with Wood, the lungs, the large intestines and the nose with Metal, and the stomach, the spleen and the mouth with Earth. The foundation of health, tranquility, and well-being rests on the perfect equilibrium and harmony of the two cosmological forces yin and yang, which continually ebb and flow. Everything is produced by union and perishes by decomposition. From the two orders of mutual production and mutual conquest the Chinese derived two principles, namely the “principle of control” and the “principle of masking”. Any of the five *xings* that conquers another *xing* is controlled by the *xing* that conquers it. For example, Fire conquers Metal, but the process is controlled by Water. Any *xing* that conquers another *xing* is masked by a *xing* that produces the conquered *xing*, i.e., Fire conquers Metal, but Earth masks the effect.

Then comes the system of the Yijing (Book of Changes) with its 64 hexagrams said to be derived from the theory of yin and yang and that of the *wuxing*, although the system was sometimes used to support those two theories instead. Traditionally the origin of the system traced back to the eleventh century BCE when the sage father of the founder of the Zhou dynasty got inspiration from two mystical diagrams, the *Hetu* (River Diagram) and the *Luoshu* (Luo Chart). These two diagrams supposedly held the secrets of yin and yang as well as the *wuxing*. In the Yijing heaven and earth, thus yang and yin, originated from *Dao*. This term probably refers to natural

order in this context but is opened to a broad range of diverse interpretations. The system of the *Yijing* was mainly employed for the purpose of divination. Besides divination it also found its use in the “explanation” of scientific phenomena, such as in astronomy and alchemy.

In traditional Chinese thought, divination and mathematics were inseparable. The word *shuxue*, the modern term for mathematics, was only first used in the modern sense in the last century when ► [Li Shanlan](#) (1811–1882) translated Western mathematical works into Chinese. Before then the same term in traditional China referred not only to divination and mathematics but also to astronomy and music. One is reminded of the word mathematics as defined by Boethius (480–524) to include arithmetic, geometry, astronomy, and music, which became the *quadrivium* in medieval Europe. In the eyes of traditional Chinese mathematicians, such as Liu Hui (fl. 263) and ► [Qin Jiushao](#) (1202–1262), divination was the loftiest form of *shuxue* while mathematics (in its modern sense) was only its common form. *Shu* was something that could be predicted by calculations, whether by means recognized by modern scholars as mathematics, such as finding the unknown number in a mathematical equation, or predicting rain in weather forecasts and telling the future using the system of the *Yijing*.

Buddhism and Daoism gradually gained ground over the Confucianists after Han China in the third century. A revival of learning during the time of Song China (960–1279) saw the neo-Confucianists attempting to cover science, particularly cosmology, within their schools of philosophy. The most celebrated among them was Zhu Xi (1130–1200), who sought to explain everything, both natural and human, with *li* (Nature’s pattern), *qi*, and *shu*, while Zhang Zai (1020–1077) applied the concept of *qi* to explain natural phenomena and moral issues. Then there was the *xiangshu* (numbers of the symbols of the *Yijing*) school that focused its attention on the elucidation, verification, and application of the system of the *Yijing*. The most famous member of the school was Shao Yong (1011–1077), who used the system to explain natural phenomena

and human affairs and to work out past and future events. His new order of the 64 hexagrams was shown by Leibniz (1646–1716) to be similar to the arrangements using the binary notation. Although Zhu Xi’s philosophy was adopted as state orthodoxy, it does not imply that it met no opposition. For example, a contemporary, Lu Xiangshan (1139–1192) developed the neo-Confucian school of Idealism or of the Mind, which was later further developed by the Ming philosopher Wang Shouren (1472–1529), who had a large following.

The earliest text on Chinese astronomy and mathematics is the ► [Zhoubi suanjing](#) (Mathematical Manual of Zhoubi), which Christopher Cullen showed recently to be a compilation of the first century. In 1973 many important discoveries were made in the excavation of a Western Han (206 BCE–AD 9) tomb in Mawangdui, Hunan province. They included a manuscript recording the ephemerides of Jupiter, Saturn, and Venus between the years 246 BCE and 177 BCE and a silk manuscript illustrating comets in various shapes. Astronomical instruments such as bronze clepsydrae and bronze sundials have also been discovered in other excavations.

The Commentary to the *Jiuzhang suanshu* (Nine Chapters on Mathematical Arts) by Liu Hui (fl. 263) was the most influential text in the history of Chinese mathematics. In 1983 the *Suanshushu* manuscript (Mathematics Book), written on ► [bamboo](#) strips, was discovered in an ancient tomb dating back to the second century BCE at an excavation carried out in Hubei province. A preliminary study shows some similarities between this manuscript and the *Jiuzhang suanshu*. Liu Hui also wrote another, but much shorter text, the *Haidao suanjing* (Sea Island Mathematical Manual), using the right-angled triangle to measure distance and height. Before the time of Liu Hui, around the year AD 190, ► [Xu Yue](#) wrote his *Shushu jiyi* (Recording Omitted Items in Mathematics). Between AD 280 and 473 the *Sunzi suanjing* (Mathematical Manual of Sunzi) appeared. Of all the problems it contains, the one that has aroused most attention among modern scholars is that of the Remainder

Theorem. The problem is to find a number, which when divided by three leaves a remainder two, when divided by five leaves a remainder three, and when divided by seven leaves a remainder two. The required answer is 23. Actually this problem involves three indefinite simultaneous linear equations of one unknown, and there is an infinite number of answers of which the required answer is the smallest. Historians of mathematics study this purely as a case of the Remainder Theorem. However, a more important application of this problem was recently revealed. It was found to be the method adopted by Chinese astronomers up to the eighth century to calculate and construct new calendars.

Several other mathematical texts were written in the following three centuries. One must note the evaluation of the ratio of the circumference to the diameter of a circle made by Zu Congzhi (429–500) and his son Zu Keng. They gave three different values, of which the most accurate was $3.1415925 < \pi < 3.1415926$. The method used by Zu Congzhi was described in his book, the *Zuishu*, which unfortunately is already lost. Chinese mathematics reached its golden age of development in the twelfth and the thirteenth centuries. During the twelfth century, mathematicians like Liu Yi and others could solve cubic equations numerically. Their writings are no longer extant, but fortunately we have the works of four great thirteenth-century mathematicians, namely ► [Qin Jiushao](#), Li Zhi (1192–1279), ► [Yang Hui](#) (fl. 1261–1275), and Zhu Shijie (fl. ca. 1280–1303). The study of numerical solutions of equations of higher degrees is yet another of the characteristics of Chinese mathematics. Li Zhi also had a great influence in the development of ► [mathematics in Japan](#).

The Chinese emperor regarded calendar-making as one of his duties that came with the mandate bestowed upon him from Heaven. The Chinese calendar took into account the apparent cycle of the sun and the cycle of the moon, both of which cannot be expressed in an exact number of days. The astronomer responsible for constructing a lunisolar calendar had to make accurate observations of the sun, the moon, and the planets, but however accurate his

observations, his calendar would eventually, in just a matter of decades, go out of step with observations. In 1972 archeologists working at the site of a Han tomb at Linyi in modern Shandong province, discovered a calendar for the year 134 BCE. Throughout the history of China no less than 100 calendars had been constructed, not to mention other unofficial calendars sometimes used in certain regions. The most renowned among the Chinese calendars were the *Dayanli* calendar completed by the Tang Tantric monk Yixing (683–727) in 727 and the *Shoushili* calendar prepared under the Mongols by Guo Shoujing (1231–1316) in 1280. They used the method of differences in mathematics to make their calculations. Accurate and new astronomical observations had to be made for the purpose of calendar making. New astronomical instruments were constructed for this purpose. Yixing, for example had to construct his own armillary sphere. The Song dynasty (960–1279) is remembered for the several large armillary spheres made for this purpose. The most famous was that made by Su Song (1020–1101). It was an armillary sphere driven by a water wheel using the principle of escapement.

In the early stages medicine and magic were indistinguishable from each other, as both were practiced by the shamans (*wu*). Shamans and doctors were together referred to as *wuyi* (shamans and doctors). During the Spring-and-Autumn Period (722–480 BCE) there were signs that physicians and shamans had already parted company. There was the celebrated physician Qin Yueren, better known as ► [Bian Que](#) (fl. 501 BCE), who was the counterpart of Hippocrates (465–370 BCE) in China. He was already acquainted with the four important diagnostic procedures used in Chinese medicine: observing external signs (*wang*), listening to sounds (*wen*), asking the patient's history (*wen*), and feeling the pulse (*qie*). These are sometimes referred to as looking, listening, asking, and touching. The earliest Chinese medical writing known to us until recently is the ► [Huangdi neiijing](#) (The Yellow Emperor's Manual of Cor-poreal Medicine). Consisting of two parts, the book appears to have been written by several

earlier unknown authors but took its final form during the second century BCE. Between the winter of 1973 and the spring of 1974 some valuable medical writings were discovered during the excavations at Mawangdui near the city of Changsha in modern Hunan province. The tomb where these writings were found dated back to the year 168 BCE and hence the medical writings concerned must have belonged to an earlier date. These are the two most ancient Chinese medical writings extant.

The earliest Chinese pharmacopoeia that we have is the *Shennong bencaojing* (Pharmacopoeia of the Heavenly Husbandman). We do not know its exact authorship and neither are we certain about when it was written, although the date could not be later than the second century. It sets a tradition followed by a long series of succeeding pharmacopoeias over a period of more than a thousand years. It mentions the *yin* or *yang* property and the indications of each medicinal substance, noting that some combinations of two or more of them are either beneficial or counter-indicative. It divides all the 365 items of medicine that it contains into three categories. Those in the first category have the efficacy of nourishing or prolonging life; those in the second are, as a rule, nontoxic and can be used to restore the constitution of the patient; and those in the third are usually toxic or have side effects. The last category is used for combating diseases. Thus the *Shennong bencaojing* catered to the needs of both the physicians and the aspirants of longevity.

While the physicians had parted company with the shamans, some of the latter devoted their attention to prolonging the human life span. Some of the substances they ingested, such as mercuric sulfide, mica, licorice, and asparagus, are listed in the *Shennong bencaojing* pharmacopoeia. The search for the way to physical immortality probably began in China at least 2,500 years before our time. It is recorded that in the Warring States Period (480–221 BCE) someone presented an elixir to the prince Jingxiang wang in the State of Qu. Some modern writers attribute the first practice of ► [alchemy in China](#) to ► [Zou Yan](#). Later on the story of the elixir told

by the shamans got the fancy of the emperor Qin Shihuangdi, who made several attempts to procure an elixir for himself so that he could live and rule his empire to eternity. Another patron of the shamans was the emperor Han Wudi, who reigned about 133 BCE. It was then that the shamans talked about making gold as the first step toward the elixir. At about the same time, Liu An, the Prince of Huainan, compiled, with the help of a group of shamans and alchemists retained by him, the *Huainan wanbishu* (The 10,000 Infallible Arts of the Prince of Huainan). Tradition says that this book dealt mainly with alchemy, especially the making of gold, but unfortunately we no longer have the complete text, and the fragments of the book now left are only concerned with magic. In the following century Liu Xiang, who was said to have inherited this book, was commissioned by the emperor to make gold for the Treasury. His failure landed him in prison.

The earliest Daoist alchemical treatise that is still extant today was written by the alchemist ► [Wei Boyang](#) in the second century AD. Entitled *Cantongqi* (The Kinship of the Three), the text is very obscure, containing a number of alchemical terms with “hidden” meanings. The use of the system of the Yijing (Book of Changes) has contributed directly to the obscurity of the text of the *Cantongqi*. Alchemy gained popularity following the work of Wei Boyang. During the fourth century ► [Ge Hong](#) wrote his *Baopuzi neipian* (The Esoteric Chapters of the Solidarity Master), showing the great advancement made in alchemy since the time of Wei Boyang. Ge Hong was at the same time an accomplished physician. Other famous physicians who were also great alchemists after Ge Hong were ► [Tao Hongjing](#) (456–536), ► [Sun Simo](#) (?581–?682), and his disciple Meng Shen (621–718). For the next 800 years or so after Ge Hong, alchemy continued to flourish and many alchemical works were written. Most of these works are lost; those that survived are included in the present version of the *Daozang* (Daoist Tripitaka), a collection of 1464 Daoist works, only a small fraction of which deal with the subject of alchemy.

In many of their experiments the Chinese alchemists used the process of sublimation and of distillation. They often made use of the reaction-vessel, called *yaofu*. Many of the elixir recipes contained toxic ingredients such as mercury, arsenic, and lead. Hence such elixirs would be quite poisonous. Quite a number of Chinese emperors showed great interest in the elixir and some of them unwittingly perished. For example, the Jin emperor Aidi died in his very prime, aged only 25, as a result of his attempt to avoid growing old. The emperor Wenxuandi of Northern Qi, on the other hand, exercised more caution. When presented with the elixir he decided that the most opportune moment to test it would be on his death bed. At least three Tang emperors died as a result of taking the elixir. Political motives might be behind the early demise of some Chinese emperors, but the alchemists responsible were quickly punished for their failure. With the evidence so efficiently destroyed the full case is difficult to investigate.

There were probably many charlatans among the alchemists, who, when their elixirs brought about the early demise of unfortunate emperors, managed to escape before it became too late. However, there were also alchemists sincerely interested in their work who believed in the elixirs they made. So strong was their faith that many alchemists must themselves have fallen martyr to their own beliefs, or become victims to mistakes in following the obscure and contorted instructions of their predecessors. The most experienced or industrious experimenters were often the most enthusiastic believers, and in the end the surest victims. In this respect the elixir mania must have acted as an inhibiting factor to the progress of chemical knowledge in China.

Many Chinese alchemists were aware of the toxicity of their products. Some tried to neutralize the poison; some recommended only symptomatic treatment; some believed that the ill effects were only side effects associated with the elixir and as such should be completely ignored; some turned to the vegetable kingdom to look for suitable ingredients; and some turned away from the material elixir and practiced “physiological alchemy” (*neidan*) following a regime of

meditation and breathing exercise. By the ninth century ► [alchemy in China](#) had already seen its best days. The alchemists gradually relied more and more on the vegetable kingdom for their raw material. Hence there was an alchemical work that included the term *bencao* (pharmacopoeia) in its title, namely the *Waidan bencao* (Pharmacopoeia of Operative Alchemy) by Cui Fang (fl. eleventh century). After the turn of the fourteenth century several books on elixir plants made their appearance. The Chinese alchemists seemed to have gone round one full circle back to the days of the ancient shamans. Alchemy merged again with the tradition of Chinese medicine set by the *Shennong bencaojing* pharmacopoeia.

Hence traditional Chinese medicine and alchemy arose from the same source. At first the shamans practiced both magic and medicine. About the sixth century BCE medicine and magic took different courses. Some shamans developed the art of prolonging human life and reached the conclusion that one had to make gold by artificial means as a first step to physical immortality. That was the beginning of alchemy. Alchemy maintained a close link with medicine, dealing only with different aspects of human life. Quite a number of alchemists were at the same time famous physicians, as in the case of ► [Ge Hong](#), ► [Tao Hongjing](#) and ► [Sun Simo](#). A preliminary study shows a close connection between alchemy and Chinese medicine in the similarities between the basic principles used in medical and elixir prescriptions. Medicine and alchemy borrowed from each other. For example, alchemical works are liberally quoted in the more important pharmacopoeias of later time such as in the *Bencao gangmu* (the Great Pharmacopoeia) written in 1596. Although the Chinese alchemists did not succeed in their quest for the elixir of immortality, they played a part as the iatrochemist in Chinese medicine. Another by-product of their experiments was that they stumbled upon ► [gunpowder](#) when some of them caused an accident when they did not exercise sufficient caution in using saltpeter and sulfur, allowing some carbon impurities to get in from the charcoal or wood that they used as fuel.

There was early intercultural transmission of scientific and technological knowledge between China and her neighbors, especially west Asia, before the Christian era. Buddhism first came to China in the second century. Scientific knowledge followed the wakes of missionary and pilgrimage activities. During the eighth century Indian monks and calendar experts, Nestorians, Arab merchants, Korean and Japanese students, and others lived together in the Tang capital Changan (modern Xian) which had a population estimated to be over one million. Mutual exchange of knowledge was inevitable. Muslim astronomers found employment in the astronomical bureau in thirteenth-century China and some Chinese astronomers could have been sent by Hulagu Khan to work in the observatory in Maragha under its director Naṣir al-Dīn al-tūsī (1201–1273). The Renaissance in Europe was influenced in no small measure by Arabic and Indian learning, but Europe also acquired knowledge of Chinese science and technology through the Arabs and the invasion of the Mongols during the thirteenth century. Since the seventeenth century science in Europe has advanced by leaps and bounds while Chinese traditional science remained in a state of stagnation. Toward the end of the sixteenth century the Jesuits arrived in China, using science as a tool to promote their mission. Science from Europe, particularly mathematics and astronomy, demonstrated its superiority to traditional science. In the latter half of the nineteenth century modern science came to China from Europe and North America, and by the twentieth century China had joined the world in the common enterprise of modern science.

Science in Japan

Nakayama Shigeru

The history of Japanese science, technology, and medicine is divided into two distinctly different periods, traditional and modern, the dividing line being the late nineteenth century when Japan started wholesale Westernization. Since the subject matter of modern Japanese development is not much different from Western development, this article deals only with the traditional and transitional periods.

The Traditional Period

The written history of Japan started approximately in the sixth century when Chinese writing, culture, and institutions were brought in by Korean immigrants. Technical professions began in Japan with the immigration of Korean experts in the sixth to eighth centuries.

The immigrants slowly settled into Japanese society, and the Chinese view of nature gradually began to take root in Japan. Thus, traditional Japanese science, technology, and medicine are basically a ramification of Chinese paradigms. In the following, we shall elucidate the points of Japanese deviation from the Chinese prototype.

Whereas the Western world of learning had an integral structure of trivium, quadrivium, scientia, or Wissenschaft, the corresponding Chinese world of learning was thoroughly structured with Confucian classics at the center of a structured bureaucracy. Scientific subjects were of peripheral importance, with mathematics and calligraphy being necessary for the civil service examination system, and astronomy, medicine, and architecture being fields with their own branch offices in the bureaucracy. The small replica of the Chinese world of learning and bureaucracy was created during the eighth century in Japan.

In principle, the Japanese Astronomical Bureau was a miniature reproduction of the Chinese bureaucracy, but a closer look reveals significant remodeling to meet local requirements. While in China the astronomical organizations that computed the ephemerides and observed celestial phenomena had important astronomical bureaux, in Japan all of these activities were subsumed under the single ► [Yinyang](#) Board, the name of which indicates a clear priority for divination. After that time, the Japanese *Yinyang* art developed into a complex of divination techniques.

Given a Chinese manual of calendrical science from which to determine basic parameters and computational procedures, there was little that local talent or preference could add. On the other hand, when unforeseen and ominous celestial phenomena were observed they had to be interpreted without delay. Thus in astrology the Japanese were thrown upon their own resources, and the practical application of imported knowledge was valued over basic theory.

It was not the regularities of the eternal truths of mathematical astronomy but the unforeseeable omens of the astrologers that attracted attention

in Japan. Whereas abstraction and involved theoretical argument were by no means rare in Chinese science, they were vastly less important in Japan.

As the Chinese influence became less noticeable from the tenth century on, the bureaucracy also diminished in strength. Throughout the medieval period, it was in family businesses rather than the government bureaucracy where those with talent enough to pass civil service examinations were employed. Kinship ties returned to their former importance.

Because they were separated from the Asian continent, the Japanese were not totally overwhelmed by Chinese influence. Japanese society was much less bureaucratic than that of China or Korea, and as a result was more able to respond to the incoming intellectual flux. The Japanese received Chinese influence selectively to meet local needs.

Meanwhile, Buddhism reached Japan from India by way of China and Korea. Although enthusiasm for Buddhism waned somewhat in China and Korea, the Japanese have retained it throughout history. In medieval times, Buddhist monks competed with official astronomers in predicting eclipses by use of their *Fu-tian* calendar. In the paradigmatic treatise of Japanese divination art, *Sukuyōkyō*, excerpts from classics of Tantric Buddhism were mixed side by side with Chinese Daoist texts. In Japanese medical classics, certain Buddhist recipes were mixed and preserved. This reflects Japanese intellectual pluralism.

The Platonic conviction that eternal patterns underlie the flux of nature is so central to the Western tradition that it might seem that no science is possible without it. Nevertheless, although Chinese science assumed that regularities were there for the finding they believed that the ultimate texture of reality was too subtle to be fully measured or comprehended by empirical investigation. The Japanese paid even less attention to the general while showing an even keener curiosity about the particular and the evanescent.

This attitude may be seen in the career of ► [Shibukawa Harumi](#) (1639–1715), the first official astronomer to the Japanese Shogun. In the

preface to his early treatise *Shunju jutsureki* (Discussions on the Calendar Reflected in the Spring and Autumn Annals, the oldest Chinese chronicle), he stated that astronomers had rigidly maintained that when Confucius dated the events in his *Annals of the Spring and Autumn Era* he made conventional use of the current calendar with little care for its astronomical meaning, so that the dates were not very reliable. "This error is due to the Chinese commitment to mathematical astronomy, so that they do not admit that extraordinary events happened in the heavens. Extraordinary phenomena do in fact take place in the heavens. We should therefore not doubt the authenticity of [Confucius'] sacred writing brush."

Once admitting, as Shibukawa did, that regular motion was too limited an assumption, one could easily conceive such notions as that astronomical parameters could vary from century to century. In the official Chinese calendar in the thirteenth century and earlier, the discrepancy between ancient records and recent observations was explained by a secular variation in tropical year length. Shibukawa revived this variation in the Japanese calendar, and ► [Asada Goryu](#) (1734–1799) extended it to other basic parameters to account for Western as well as Eastern observations then available to him.

The variation terms used in Japanese astronomy were too large to survive empirical testing, and were eventually discarded. It is, however, noteworthy that their cosmological outlook was so flexible that they accepted the notion that all astronomical parameters were subject to change and the whole universe was changeable, while in the West the Aristotelian notion of an unalterable universe was followed rigorously, and irregular motions in the sky were inconceivable.

In early Chinese history, higher mathematics was always associated with calendrical science, in terms of solving indeterminate equations for ascertaining the time of grand conjunction. In Japan, interest in mathematics was also raised in connection with calendrical science in the seventeenth century, and was soon developed as mathematical puzzles to be enjoyed by hobbyists, in the same way as there were enthusiasts of flower

arrangement and the tea ceremony. This form of Japanese mathematics called *wasan* was mostly viewed as a popular art. It was not considered a scholarly activity.

I shall not attempt a conceptually rigorous definition of scholarship and hobby here, but merely note that scholarship is usually thought to have some public function while hobbies are regarded as private indulgences which may or may not have significant social value. While art does not require legitimation, scholarship does, and there has to be some basis on which to differentiate one from the other. Some kind of legitimation was found to be necessary for mathematicians and one way of doing so was to invite Confucian scholars to write prefaces to their books, in effect borrowing Confucianism's prestige.

The Japanese mathematicians were generally socially marginal curiosity seekers. During the Tokugawa period, mathematics was not formally recognized by the government. The Tokugawa mathematical tradition existed entirely in the private sector and had no official support. Whenever scholars demand legitimacy from society, they display a sense of mission which reinforces their commitment. This sense of mission is associated with the rise of professions, but the Japanese mathematicians cannot be called professionals.

With the use of mathematical rods, Chinese mathematics developed quite sophisticated algebraic formulae. Building on the Chinese tradition, a significant development was made by Japanese mathematicians to develop numerical algebra into symbolic algebra by writing on paper and making it possible to obtain a more general treatment. Curiously enough, the formulae of *wasan* resemble modern algebraic formulae but they are written vertically. However, due to stylistic differences, there was no intercourse between Japanese and Western developments in mathematics.

Wasan mathematics developed a unique custom in the formative period consisting of the posting of mathematical problems called *idai* (bequeathed questions). A mathematician would post scores of problems of several kinds at the end of a book and then publish it. Another

mathematician would post answers to these problems and present his own in the same manner. According to convention, yet a third mathematician would post answers to these problems and issue his own in relay fashion. This mechanism of *idai* caused a chain reaction and greatly stimulated the formation of *wasan* groups. The tradition began with 12 problems from the *Shinpen Jinkoki* published in 1641. A succession of mathematical lineages soon developed and reached their peak during the life of ► [Seki Kowa](#) (Takakazu). Practically all of the important problems in the history of *wasan* date from the period above.

Another feature of *wasan* development was the *sangaku* (mathematical tablet) form that came in the later phase. These tablets included both problems and answers and were dedicated at shrines. The best mathematicians made their accomplishments known through books, but it was largely the custom of *sangaku* which supported the activities of the *wasan* enthusiasts. That *wasan* was a hobby which cost money to pursue is best shown by the elegant diagrams which embellished such work. In fact, the offering of *sangaku* had a strong attraction as it showed a desire to keep their work on more or less permanent view.

Chinese natural philosophy developed certain abstract concepts in ancient times. The *qi* concept, one of the basic ideas which appeared in the *Huangdii Neijing* (The Yellow Emperor's Internal Classic), the earliest Chinese medical compilation, is today interpreted as something akin to energy which is imponderable but permeates and circulates in the macro- as well as the microcosmos. When the *qi* concept was introduced into Japan, medical doctors tended to interpret it as materialistic, unable to comprehend such a highly abstract concept of imponderable energy. Given the difficulty of understanding the subtleties of Chinese philosophical speculation, the Japanese physicians adopted a more simplistic, pragmatic, and empirical approach.

For instance, certain tumors and internal swellings were thought to be stagnated or congealed *qi*. Indeed, the seventeenth-century Japanese physician, Goto Gonzan, attempted to

explain the cause of all medical disorders by stagnation of this kind.

Traditional Chinese medicine was concerned primarily with function and only secondarily with tissues and organs. Internal disorders were never local in Chinese medicine. The major physiological and pathological theory was to regulate energy flow internally and externally between the micro- and macrocosmos, so that holistic diagnoses could be applied. They depended heavily on pulse diagnosis as the indication of energy flow. More materialistic Japanese physicians such as Yoshimasu Todo (1701–1773), however, developed stomach and abdomen diagnosis by touching the location of disease, rejecting the traditional pulse diagnosis. Yoshimasu, the foremost figure of the radically critical school, declared that the *qi* of the universe had nothing to do with medicine. This group was prepared to take a position much closer to that of the solidists in the West than had been possible in Japan at an earlier time. Functional analysis lost its importance, and the physical organs could be studied for their own sake. This was nothing less than a gestalt change.

In accordance with the extension of the materialistic inclination of Japanese physicians, they were interested in anatomy and found that Western schema were a great deal more accurate than the Chinese anatomical charts. In mathematical astronomy and calendrical science, Western superiority in accuracy was quickly recognized. In medicine, there is good reason to doubt that there was any difference in therapeutic efficacy before the late nineteenth century. It is above all in the comparison of anatomical charts that the strength of Western medicine would be apparent.

In the second half of the eighteenth century, Sugita Genpaku took up the study of anatomy because it seemed the most tangible, and therefore the most comprehensible, part of Dutch medicine. Following the solidist breakthrough, Sugita's successors in medicine studied physics and chemistry and opened up the world of modern science. The Copernican influence was minor by comparison, because the Japanese cosmos had not been defined by religious authority. The impact of anatomy challenged the energetic and functional commitments not only of

medicine but also of natural philosophy. Its effect was bound to be revolutionary.

The learned treatises of the Chinese and Japanese medical traditions lacked terminology not only for brain function but also for mental processes. It was only later scholars with considerable knowledge of Western anatomy, such as Sugita Genpaku, who could abandon the Chinese tradition entirely and display as much anatomical interest in the brain as in the viscera.

Materia medica and natural history books were brought first from China and later from Holland. The first thing for a Japanese natural historian to do was to identify local species with imported Chinese books. This identification work endowed Japanese scholars with new insights into comparative study. While the original Chinese texts were intended for the collection of medicinal herbs for pharmaceutical purposes, the Japanese developed this study into a natural history of visual observations for identification.

In feudal Japan, all occupations were hereditary. The post of official astronomer to the Shogun was created to recognize the personal achievement of ► [Shibukawa Harumi](#), and was passed down to his descendants. It had no significance beyond the technical, and thus was of no interest to the generalists. Those who held technical posts of this kind, such as medical doctors and Confucian scholars, were from the beginning separate from the general samurai bureaucracy.

When the official astronomer and his subordinates were compiling the ephemerides, Confucian scholars were not consulted. The astronomers had inherited the tradition through their family line since medieval times. At the time of a calendar reform, once every hundred years for a Chinese-type lunisolar calendar, the descendants were usually incapable of innovative work, but able to perform the routine calculations necessary for the distribution of the yearly calendar according to a given formula. In most such cases, talented astronomers in the private sector were appointed to the post of official astronomer. Beginning with Shibukawa Harumi, the number of such hereditary official astronomers amounted to seven families toward the end of Shogunate rule.

Often professionals were encouraged to adopt talented young boys rather than their own sons. Under the rules of samurai society in the Tokugawa period, only the first son was entitled to inherit the family stipend. Later born sons were adopted by other sonless samurai families or left to find ways of obtaining their livelihood themselves. For either, they had to show their ability by studying hard. These younger sons would provide Japan with a pool of talented professionals.

In Japan, there was no social or political reason for a single philosophical orthodoxy. Although nominally based on the centralized Chinese model, Japanese feudal society remained multifocal, consisting of the Shogunate and a hundred fiefs. Thus freedom to choose between several paradigms seems to have been as desirable as the search for a unitary principle was in China.

In China and Korea, the official character of science and learning was rigidly maintained by adherence to the civil service examination system. The Japanese imitated the Chinese bureaucracy for only a short time in the seventh and eighth centuries, and subsequently this failed to take root in Japanese society. It was only in the last quarter of the nineteenth century with the establishment of a modern government system that a centralized bureaucracy complete with civil service examinations emerged. During the Tokugawa period, it was centralized feudalism, in which the Tokugawa government had overwhelming power but in which each fief government was able to maintain a degree of autonomy by having their own independent schools, bureaucracy, and policies, in competition with other fiefs.

The Tokugawa Shogunate wanted to instigate centralized civil and medical service examinations but was unable to impose such a system on the fief governments. As a result, there was no rigidly maintained state orthodoxy of science and learning, although the exclusion of Christian tenets was executed with considerable harshness. In short, the Japanese have enjoyed the merits of multiculturalism. It is not the kind of multiculturalism which involves the peaceful coexistence of different races in one society but rather signifies the acceptance of different cultures by largely one single group.

Science and learning had been substantially privatized and able to respond to imported foreign ideas by the late eighteenth and early nineteenth centuries. Even during the semiseclusion period under the Tokugawa Shogunate, the activity of Dutch learning was practiced by city intellectuals, medical doctors, and merchants in the private sector. Only after the Western threat of invasion became substantially felt in the nineteenth century, particularly after the news of the Opium War and the arrival of Commodore Perry's gunboats in 1853, did the knowledge of Western learning become the business of the public sector. Samurai became interested in Western [military technology](#), finally overthrowing the feudal government and replacing it with a centralized state.

From the seventeenth century onward, when Western knowledge began to exert claims of its own against the backdrop of Chinese learning, Japanese thinkers were critically attentive. As soon as they were convinced that European technical knowledge was superior, the Japanese switched to the new paradigm with remarkable speed. They quickly modified their attitudes and oriented themselves toward achieving certain desirable goals that had been reached in the West. For the Chinese, the encounter with European ideas was traumatic; to accept them was to reject traditional values, and to reject them would leave them with no defense against dismemberment by Western powers. For the Japanese it was merely the appearance of another paradigm to be accepted in their eclectic manner. The Japanese were flexible enough to accept the Western paradigm without strong resistance.

The Transitional Period

Let us now turn to the occupational support groups who successively played a leading role in the introduction of Western science to Japan.

Astronomers and Interpreters

The adoption of Western "barbarian" astronomy in the seventeenth century by the Chinese dismayed conservative elements in Japan. However, it did not promote the desire in others for a similar

change in the Japanese calendar, which was modeled on that of the ancient Chinese. As has been mentioned, the eighth Shogun Yoshimune and his court astronomers recognized the superiority of Western over Chinese astronomy, but astronomers were primarily government bureaucrats or technicians whose scope remained limited to their assigned duties of drawing up the official calendar. Their interest in Western science was limited to the precision of astronomical data and methods of calculation, and they made no attempt to jeopardize their hereditary posts by entertaining revolutionary paradigms such as were developing in Europe at that time.

Professional interpreters at Nagasaki were the most well versed in the Dutch language, through which they must have become acquainted with the concepts of Western science. But again, they were also hereditary government officials who remained within the boundaries of their duty of faithful translation and nothing more. Neither official astronomers nor interpreters published their work for general audiences.

Independent Scholars and Physicians

From the late eighteenth century on, a sizeable number of Dutch books containing the term *Natuurkunde* (study of nature) found their way into the country and aroused the interest of various independent scholars in the private sector who set about translating them, although their foreign language skills were much inferior to those of the Nagasaki interpreters. The majority of these "Dutch scholars", as they came to be called, were avant-garde physicians who were primarily freelancers, with no strict subordinative links to the governing elite or subsequent interest in maintaining an existing *status quo*. Thus they were not inhibited in stepping out of their line of work and were free to extend their interests to anything Western except perhaps the Christian doctrine. Astronomy was the first area in which people sensed that the West was superior, but the notion that the West was superior in other fields of scientific endeavor first spread among these independent physicians.

As they inched their way through Dutch texts, they realized that Western science was more than

a variant of the natural history line of their own tradition. As they saw it, its essence could be translated as *kyuri* (literally, investigating the principles of things, a new Confucian term, or “natural philosophy”, being a systematic and fundamental investigation and consideration of the nature of things). Thus, although at first there was no clearly established tradition for the term, *kyuri* was later to become the most common, and given the vocabulary of the period, it was an informative translation. In recognizing an enquiry into principles at the bottom of such traditional practical studies as medicine and calendar-making, in becoming aware, i.e., of natural philosophy or physics, they also grasped the hierarchical structure of modern science, from basic to applied. Above and beyond the culturally bound achievements of Western science, they seemed to have sensed that it contained a revolutionary paradigm, since the belief in underlying laws in Nature which could be formulated was weak in Japanese traditional thought. This was in marked contrast to the official astronomers who looked upon science as something that could be handled at the technical level and assigned it only a supplementary role.

The physicians recognized the importance of physics and chemistry as the basis of medical work, and several founded schools for the teaching of Western medicine. Their students, during their apprenticeship and internship days, moved from one school to another in major medical centers like Nagasaki, Osaka, Kyoto, and Edo (Tokyo), and played a role of diffusing knowledge of Western culture as well as medicine. While some physicians remained in the practice of medicine, others turned to the teaching of the Dutch language and even the discussion of international knowledge and politics and also founded schools for such. Thus, the cultural influence of the physicians was more considerable than that of the astronomers who limited their activities to the translation of technical works.

But these support groups were by no means adequate preparation for the reception of contemporary science. The Dutch scholars were still only amateur supporters of uninstitutionalized

paradigms, comparable in this respect to gentleman members of the Royal Society. Their schools were few and regarded on the whole as avant-garde. Had they flourished in the seventeenth and eighteenth centuries their work might have had greater consequences. By the mid-nineteenth century, however, modern science in the West had entered the systematically structured world of the university and reached new advanced levels. Reception of learning that was now systematically pursued in Europe within the structures of the university required the creation of an institutional system. It had to be met not by self-taught amateurs but with professional scientists who had received a modern systematic education. These early scholars were not aware of the institutionalized aspect of Western science up until the mid-nineteenth century, remaining bookish translators of the *kyuri*, paradigmatic aspect of Western science.

Samurai

The Opium War between the Chinese and Western colonialists created concern among the samurai cognoscenti, but Commodore Perry's visit to Japan in 1853 and the subsequent threat of war caused all samurai to realize that the Westerners' science was needed for national defense. As a result, young samurai flocked to the schools of Western learning established by physicians. As they were traditionally the ruling class, and in time of war the warriors, it was natural that samurai interest in Western science and technology training was based on more real and pressing needs than reception of and support for particular scholarly paradigms.

First, they tried to learn the Western art of manufacturing firearms, but soon realized that it was impossible to catch up and compete with Western forces by a crash project of manufacturing cannons. They could purchase hardware, but what was really needed was the software of Western military training and tactics. Moreover, the acquisition of Western military discipline was one of the contributing factors in the overthrow of the ruling Tokugawa family by anti-Tokugawa samurai and the subsequent establishment of the Meiji government in 1868. The samurai

recognition of Western science was therefore political rather than cultural.

After the revolution, convinced that Western scientific learning was essential, the ruling class set out to disseminate their conviction through the establishment of an educational infrastructure. With Meiji effort and initiative, modern science was fully assimilated in a wholesale introduction through governmental institutions rather than a piecemeal cultural infiltration, as in the previous era, and modern scientific and technological professions became the artificial creation of the new Western-oriented government.

The main practitioners of these new professions were former samurai. In the past they had received hereditary family stipends in exchange for their loyalty to the feudal powers, the Shogunate or local feudatories. But in the 1870s, efforts were made by the Meiji government to curtail the inherited family stipends of the samurai class as a step toward social modernization. While other classes, farmers, artisans, and merchants, could continue to be engaged in their inherited vocations, samurai completely lost their guaranteed source of income. Consequently, they had to find new ways of living independently. Since the samurai could not compete with other classes in the fields of traditional occupations like agriculture and medicine, science and technology was one of these new fields into which jobless samurai were attracted and invited. Almost all of the early graduates of the engineering colleges were samurai. Even as late as 1890, the percentages of Imperial University samurai graduates in engineering and science were 86 and 80, respectively.

Thus, Japanese modern science and technology professions were, in the beginning of their formation, very much “samurai-spirited.” The samurai were the class long accustomed by mental habit to think in terms of public affairs and by behavior patterns to play the game of public office. Unlike the European pattern in which science and technology training was one experience of the rising bourgeoisie, the new Japanese scientific and technological professions in the last quarter of the nineteenth century were dominated by the proud old samurai class, comprising the top 5 % of the total population.

Table 1 summarizes the sequence of support groups’ thrust toward Westernization in Japan.

In the first stage, Western science was confined merely to technical knowledge by technicians in the government sector. In the second, Western knowledge in the form of its revolutionary paradigms was garnered by vanguard physicians but they were alienated from the central power structure. Only in the third stage was Western science fully admitted into the power structure, and after the Meiji Restoration, through institutionalization, it was recognized as a most legitimate study for the youth of the samurai class.

The modernist samurai leadership soon established a policy of Westernization in which the establishment of Western-style educational institutions occupied a central position. During the 1870s and 1880s greater emphasis was placed on science and technology in the Japanese educational curriculum, from elementary school to university level, than in any other nation. For instance, mathematics and science occupied about one-third of the school curriculum at the lower grades (first 4 years) and two-thirds at the

Science in Japan, Table 1 The sequence of support groups’ thrust toward Westernization in Japan

Occupation	Astronomers and interpreters	Physicians	Samurai
Leading century period	Eighteenth century	Late eighteenth to early nineteenth century	Mid-nineteenth century
Interest	Technical	Cultural	Political
Status	Technicians	Freelancers	Planners and administrators
Role	Referees of superiority	Diffusion and popularization	Institutionalization

upper grades of the 8-year elementary education, though due to the shortage of qualified teachers available, it is somewhat questionable to what extent these ideal plans were put into practice. At the tertiary level too, the emphasis on science and technology was evident in the high percentages of graduates in scientific disciplines of Tokyo University (85 % in the 1880s). In Europe in the nineteenth century, the voluntary activities of scientific or professional societies usually preceded their inclusion into the university curriculum. In the case of Meiji Japan, however, and as is generally the case when a foreign discipline is artificially transplanted under state sponsorship, this process was reversed. Tokyo University was established as an indispensable part of the modern technocratic bureaucracy. Graduates in science and technology were mostly samurai descendants who were accustomed to working in the public sector and inspired in technocratic policy-making, rather than by engineering apprenticeship of the traditional artisan class. They were adaptable in “public science” initiated by the government, which was indispensable for the operation of a modern state, in areas such as geographical and geological surveys, weights and measures, meteorological observations, sanitation, printing, telegraph and telephone system, military works, railways, and surveys of national resources.

In addition, the government participated in private entrepreneurial activities, constructed and managed pilot plants, and guided and subsidized new kinds of industries. Their enterprises were, however, from the beginning exposed to financial risk. Many of the projects of the Ministry of Technology eventually proved to be too far ahead of their times, as they intended to introduce the technology of an industrialized society into a preindustrial environment. For instance, their railway construction and textile mill enterprises were economically unsuccessful at the time.

Some of the samurai experiments in the public sector were successfully transferred into the private sector, where they were transformed to the market-oriented “private science” of the traditional artisan, such as Toyota Sakichi, the founder of Toyota Motors. The privatization of science phase was finally completed after World War II.

Science in Korea

Jeon Sang-Woon

Korea is a nation with 5,000 years of history. Located on the periphery of East Asian civilization, it was greatly influenced by China. However, Koreans have developed a culture and tradition independent from that of the Chinese. At the same time, the history of Korean science can be regarded as a branch or an adaptation of Chinese traditional sciences, although, in most cases, Chinese sciences and technology were not adopted in their original form.

Korea had its own unique Paleolithic Age some 500,000 years ago. Some of the tools of the Paleolithic Age found in Korea are not found in any other parts of East Asia. The Korean people of the Neolithic Age differed from the Chinese people in that they belonged to what is often called the northern race. Unlike the lineage from the Paleolithic Age, the lineage from the Neolithic Age has continued to survive down to the formation of the Korean people. Elements of

the Neolithic Age combined with each other and then with elements of the Bronze Age in the formation of the Korean people.

The highly developed Bronze Age culture in Korea around the year 1000 BCE was influenced by a northern culture that was different from the Chinese scientific one. Chinese science and technology were adopted on the basis of an indigenous technological tradition. Koreans have always attempted to reshape Chinese technology whenever it was introduced into Korea to make it uniquely Korean and to develop new technology.

Typical examples of this kind of endeavor are found in the bronze sword and mirror. The lute-shaped bronze sword and Korean-style sword and the bronze mirror which has a thick lined design with two knobs, and the thin lined mirror, are uniquely Korean bronze instruments. These instruments reveal unique design and casting skills indicating the highly developed state of bronze-making technology. This technology in Korea has a different lineage from that of the Chinese. This is found in the chemical make-up of the bronze instruments themselves. Even the earliest bronzes found in Korea there are alloys of zinc and bronze.

Koreans demonstrated a special creativity by developing an advanced skill in bronze production and alloy making. Bronze makers in Korea used both mud molds and stone molds to produce bronze items. Stone molds, which are frequently found in Korea, are very seldom discovered in China.

Casting technology utilizing stone molds led to the development of a unique iron ax casting system that developed from the third century BCE in Korea. In this period iron axes were produced in massive quantities by using stone molds. It is a commonly held belief that the Iron Age in Korea started in the fifth to fourth centuries BCE with the introduction of Chinese iron culture. The mass production of iron axes can be explained as the creation of a new technology, which would not have been possible if there had not been an autonomous tradition of iron technology in Korea.

The development in iron-casting technology brought about a dramatic increase in agricultural

production on the basis of the mass production of farm instruments. Iron ingots of the late Iron Age found in the southern regions of the Korean peninsula are unique symbols of power and wealth. Iron ingots developed by Koreans spread to Japan, setting in motion the development of an iron culture there.

The widespread use of iron brought about new kinds of earthenware. Kaya culture (or Kimhae culture) of the region produced hardened quality earthenware produced through the combination of the technology of the indigenous people of the area (who were known for their designs which lacked ideogrammatic characters) and Chinese ashen-earthenware skills.

Other regions on the Korean peninsula, such as Koguryo, Paekche, and Silla, were also developing a technological culture. The people of Koguryo, Silla, and Paekche each constructed their tombs in unique ways. The painters of the Koguryo tombs painted their walls with individual and powerful lines and colors. The many kinds of pure gold objects discovered in kings' tombs, with their distinctive designs and refined inscriptions, testify to what seems to have been a highly refined manufacturing technology.

Besides those kinds of technical cultural traditions, several examples of scientific inquiry are known to have been written in the Three Kingdoms period (first century BCE-seventh century AD). Among the most outstanding are the developments in astronomy and medicine. Records indicate that Koguryo had maps of stars in the sky inscribed on stones, and a special astronomic observatory. The paintings of the stars found in a mural of Koguryo support this likelihood. Paekche also had astronomical observatories, and special calendrical specialists were appointed in the sixth century.

The Ch'omsongdae observatory in Kyongju is symbolic of the astronomical enterprise of the Three Kingdom period of Korea. Ch'omsongdae, a stone brick edifice, built in AD 647, is the oldest surviving astronomical observatory. The delicate aesthetic lines that characterize Ch'omsongdae are a symbol of the Korean sense of beauty. Records of astronomic observations dating from the Silla period are indications of very active

institutionalized astronomical observation in that period. Astronomers in Silla learned calendrical studies from the Chinese, but were not content with just learning or copying from them. They endeavored to develop their own kind of astronomy. Ch'omsongdae is a valuable part of the heritage of their efforts.

Although actual records of medical prescriptions for long life and for the curing of diseases are scanty, they enable us to picture the systematic herbal medicine practiced in the period.

The period of Unified Silla is best represented by the great quantity of surviving remnants and records. Korea achieved a high level of creative development in science and technology in this period.

The Sokkuram grotto and the Darani scripture, among others, are representative of the achievements of Silla science and technology. The grotto, the most highly regarded edifice left by the craftsmen of Silla in the eighth century, is seen as the highest point in traditional architecture because of its geometric design and daring construction skills. There is no doubt that the Sokkuram grotto was a copy of a rock cave temple in China. However, while the Chinese edifice was built into a natural rock cave, the Sokkuram grotto is an artificial stone cave created on the basis of a harmony of various compositions including circles, spheres, triangles, hexagons, and octagons.

Silla master craftsmen also produced a number of beautiful bells. They successfully combined ancient Chinese bells and tinkle-bells in creating a unique Silla style. A special feature of the Silla bells is found in the dragon shaped hooks for hanging them. Historical records assert that Silla's craftsmen produced an alloy of bronze combined with copper, tin, and lead for a better sound. This was found to be true in a chemical analysis. The Chinese naturalist, ► [Li Shizhen](#), wrote in his *Bencao Gangmu* that "Persian bronze is good for making mirrors and Silla bronze for making bells." The bell preserved in the Kyongju National Museum was made in 771. It has a height of 3.3 m. Its solemnity and the arrangement of its design patterns are typical of Silla bells.

Master craftsmen of Silla began developing wood print type in the early part of the eighth century. The scroll of Darani scripture found in 1966 was assessed to be a wood type print on white hammered paper produced between 705 and 751. This makes it the oldest surviving printed material in the world. On the basis of surviving evidence, this would prove that printing technology was invented in Korea prior to its development in China. Whatever the merits of this claim are, the fact that Silla technology had developed, in the eighth century, to the level of producing wood type print, is a significant demonstration of its technology. It indicates that the gap between the level of technology in China and Silla was not very wide.

The science and technology of Koryo developed on the basis of the achievements of the sciences and technology in Silla. They were also greatly influenced by the Sung and Yuan dynasties in China, and there are signs of the indirect influence of Islamic scientific and technological culture. The representative achievements of science and technology in Koryo are the development of wood block printing, the invention of bronze type printing technology, and the development of Koryo celadon.

Wood block printing in Koryo developed as a result of the aristocratic interest in print copies of calligraphy in pine wood blocks. It was also stimulated by a religious motivation. Buddhist scripts were made into wood type in order to draw on the power of Buddha in the struggle against the Mongol invasion. Eighty Thousand Scriptures, the world's largest and oldest surviving wood block printing set known, was also produced out of this motivation. The printing of the Eighty Thousand Scriptures is regarded as the highest level of technology in wood block printing.

The invention of a bronze type printing system was created from a totally different motivation. Koryo, having less demand for books than China, could not maintain the enormous amount of wood blocks, time, and labor to produce a variety of kinds of books. Bronze type was invented as a solution to this problem.

Ceramic type printing was invented by Bi Sheng in the China of the eleventh century.

However, a metal type printing system was not established even by the fourteenth-century because of the difficulties in casting and the ink and paper needed for metal type printing. However, all these were possible with the science and technology available in Koryo. There, craftsmen knew of the technique of producing sand molds to make bronze print type, and were already producing oil ink suitable for printing with metal type and good quality paper. Because of this, the master craftsmen of Koryo were able to invent bronze type from wood type.

The central element in making bronze type was making sand molds. This was one of the greatest contributions in the development of printing technology. It may have been developed from the accumulated knowledge from production of various bronze vessels and casting of the grand bells.

The craftsmen of Koryo were successful in developing their skills for making celadon. They also adopted the inlaying method, which until that time had only been used in metal ornament making, for celadon making. This illustrates that, while Koryo celadon skills were adopted from Sung China they were never a simple copying of the Sung products.

Astronomy and herbal medicine were also two of the central pillars of science in Koryo as in the previous dynasties. Koryo scientists also developed geography. Major efforts in astronomy in the Koryo period were in observational astronomy and in calendar making. Official records of astronomical observations contain records of observation over 475 years. Among the records, there is a record of 132 occasions of an eclipse of the sun. This is on a par with the astronomic records of Islamic astronomers. There are also notable observations of sunspots.

A systematic foundation of herbal [▶ medicine in Korea](#) was established from the sixth to the seventh centuries at the height of the Three Kingdom period. It came as a combination of traditional medicinal prescriptions and the influence of medical theories from China. A system was developed for utilizing herbs found in Korea. *Bencao jingjizhu* (The Shennong Pharmacopoeia with Collected Annotations) written by Dao

Hungzhang contains 11 medicinal herbs that originate from Korea. And *Ishimpō* (Tamba no Yasayori's Collected Prescriptions), a famous medicinal book in tenth century Japan, contains various quotations of prescriptions from medical texts from Paekche and Silla. By the ninth century, 22 kinds of medicinal herbs originating in Korea were recorded in the medicinal texts used in China and Japan. A national medical school was established in the tenth century, and national examinations for medical practitioners were introduced. In the twelfth and thirteenth centuries, Sung medical science was introduced into Korea, while native prescriptions of local medicines emerged in Koryo in the form of three volumes entitled *Hyangyak kuguppang* (First-aid Measures with Local Medicines). This represented the first medical text describing herbal medicinal practice in the Koryo period.

In the early period of the Choson dynasty, efforts to create an independent culture brought about a forceful development of science and technology. In 1402, King Taejong proceeded with the development of bronze type print despite strong opposition from high ranking government officials. However, the books printed with the newly developed type (*kemi*) were not of better quality than the books printed with wood type. Furthermore, it resulted in lower efficiency in printing one kind of book, and it did not bring about any improvements in cost and labor productivity. It was a low efficiency technology. However, this project provided the basis for greater improvements when the succeeding king adopted it as a state-funded program. As a result Choson type printing developed to a state of perfection.

Achievements in science and technology reached their highest point during the King Sejong period, which is regarded as the golden age of Korean traditional science. The invention of the rain gauge is one of its achievements. Rain measuring instruments and watermarks were developed between 1441 and 1442, enabling the scientific measurement of rainfall. The invention of a cylindrical rain gauge resulted from efforts to obtain a precise measure. As a result the scientists in the court of King Sejong were able to develop a

scientific method for the quantitative measurement of natural phenomena. Government officials maintained the measurement and recording of rainfall throughout the country, utilizing a highly systematic method, for over 400 years.

New astronomical observatories were built during the reign of King Sejong. The great equatorial torquetrum observation platform built in Kyongbok Palace contains a torquetrum, armillary clock, armillary sphere, gnomon, direction markers, an automatic striking clepsydra, a jade clepsydra, and various other kinds of sundials. In order to construct these astronomical observatories, which took 7 years to complete, King Sejong sent mathematicians, astronomers, and technicians to China to study astronomical observational instruments. Scientists designed an astronomical instrument that was modeled on the Guo Shoujing system of the Yuan dynasty in China. However, major aspects of the instrument were modified to reflect Korean characteristics. The astronomical observatory built through such a process was the largest of its kind and among the best equipped in the fifteenth century.

Astronomers of the King Sejong period developed an independent calendar on the basis of their observations and calculations. The publication of the calculation of the motions of the seven governors, the inner and outer parts (*Ch 'ilchongsan Naep 'yon* and *Ch 'ilchongsan Oep 'yon*), is the product of such efforts. The outer part is regarded as one of the most authoritative texts written in Chinese characters on Islamic astronomy and calendar science.

The scientific achievements of the King Sejong period were found in all fields of endeavor. Koryo celadon was developed into Punch'ong ware by early Choson craftsmen to produce unique Choson celadons that differed in style and quality from Koryo celadons. A blue and white porcelain was first imported from China during the King Sejong period and began to be produced in Korea from the middle of the fifteenth century. However the geometric shape and design of the porcelain were entirely different from the Chinese originals.

► **Military technology** also developed unique characteristics in the early period of Choson. The

development of Choson style firearms and turtle ships are representative examples. Firearms began to be used widely from the late Koryo period after introduction of the skill from China. However, by the King Sejong period, firearms production in Choson had abandoned a great many of the Chinese features leading to the development of unique firearms. By totally recasting the firearms, which were improved to strengthen the national system, the Choson court, they were modified and standardized until they had their own style.

There were also notable achievements in geography. The map of the world drawn by Choson geographers in 1402, while based on some of the central maps in China, was a more complete one. Although it did not overcome the Chinese world view, it contained a depiction of Europe and Africa and the Far East which can be said to make a true world map with the most up-to-date geographical knowledge.

In the King Sejong period, actual national measurements were undertaken to produce a complete map of the country.

The map of Choson produced in the fifteenth century, currently preserved in Japan, is a map of the highest quality in comparison with others produced in the same period. Geographical scientists in the King Sejong period endeavored, in addition to making maps from thorough field surveys and study of literature, to do proper geographic work that included national and provincial maps.

The field of medicine experienced a total systematization and concentration of Korean herbal medicine and Oriental medicine. Study of local medicinal herbs was collated into a basic foundation for herbal ► [medicine in Korea](#). It was developed into a comprehensive system for prescription. The *Hyangyak chipsongbang* (Great Collection of Native Korean Prescriptions), in which a total of 703 Korean native medicines were included, was completed in 1433. Concurrent with these efforts was the editing and publishing of *Uibang yuch 'ui* (Classified Collection of Medicinal Prescriptions). This was a medical encyclopedia, completed in 1445, which incorporated 153 different

Korean and Chinese texts, and was regarded as one of the greatest medical texts of the fifteenth century. Also, the *Tongui pogam* (Precious Mirror of Eastern Medicine) was completed from 1556 to 1610 by Hochun.

Agricultural technology also experienced great development in the King Sejong period. Much of the agricultural technology in Korea until this period was based on Chinese agricultural texts. However, they could not provide appropriate guidelines for farming in Korea. To provide these, an agricultural technology text, *Nongsa chiksol* (Theories and Practice of Farming), was edited and published in 1429. This book surveyed the various farming methods in different fields and summarized the most developed and practical methods. This book contributed greatly to the improvement in agriculture in Choson and became the basic farming textbook.

However, Korean traditional sciences suffered a series of ruptures along with their creative development. A number of foreign invasions which decimated the entire territory disrupted the creative tradition in Korean scientific endeavors. The history of Korean sciences and technology is at the same time a history of these efforts. The introduction of Western science and the efforts to systematize the traditional sciences and technologies by “Sirhak” scholars from the seventeenth to the eighteenth centuries is just one example. These scholars advocated practical learning (*sirhak*) under the slogan *silsa kusi* (verification of truth on the basis of factual studies), and accepted some of the little European science that came their way. They thus began what might have become a scientific reformation because they were influenced by modern science and technology in Europe through Qing China, where the same kind of movement had been going on for some time, partly as a reaction to mystical tendencies in late Confucian philosophy. Sirhak scholars pioneered new frontiers in scientific and technological theory and scientific philosophy. However, their efforts were frustrated because of the onset of another round of invasions.

Science in Ottoman Turkish

B. Harun Küçük

University of Pennsylvania, Philadelphia, PA, USA

Until the eighteenth century, Turkish was the language used in administration, not the language of learning. Just as the primary language of early modern European science was Latin, the language of early modern Ottoman science was Arabic. Prior to the nineteenth century, writing in Turkish meant writing for the lay elite. Until the eighteenth century, the *medrese* (Islamic college) and the *tekke* (Sufi lodge) were the main sites of learning. Mehmed II's fifteenth century *medrese* reform firmly placed the exact sciences within the orbit of higher learning, while Süleyman I's sixteenth century medical *medrese* helped create the Ottoman “learned doctor.” *Tekkes*, on the other hand, were home to the occult sciences, especially alchemy.

Over the seventeenth century, the lay elite developed a stronger relationship with learning. This was evident in Mehmed IV's and Ahmed III's large-scale translation and compilation projects in the naturalistic and the humanistic disciplines. Unlike Arabic-language books, most books in Turkish were written for a patron – the

Sultan himself or an administrator of high rank. As such, the Turkish language books help us monitor the intellectual trends within the Ottoman administration. The extant evidence suggests that from the seventeenth century onward, the patronage of vernacular authors working on naturalistic subjects was prevalent. Some of these authors also leveraged the position of their powerful patrons to advocate new ideas or to affect a break with the Islamic tradition. However, the fields that broadly fell under the Aristotelian notion of theoretical philosophy (physics, metaphysics and pure mathematics) remained the domain of *medrese* until the establishment of modern, state-run, institutions of higher learning. Consequently, philosophical literature of this type is exceedingly rare in the Turkish language. By contrast, we find a large number of Turkish manuscripts on scientific practice, such as clinical observations, drug recipes, instrument manuals, and portolans [sailing directions].

By the nineteenth century, the Empire's medical and military elite were firmly under French and German influence. As the Ottoman government forged critical alliances with European powers, it also began to use a greater number of European experts and to send students to Europe. While our knowledge of scientific practices in the nineteenth century is still lacking, European science increasingly became the standard idiom of naturalism as the century progressed.

Astronomy and Astrology

The vast majority of astronomical literature in the Ottoman Empire was in Arabic, intended as it was for *medrese* students and *medrese*-trained timekeepers (*muvaqqit*). From the seventeenth century onward, one finds an increasing number of Turkish works dealing with both mathematical astronomy (*ilm-i hey'et*, *ilm-i ziccat*) and with judicial astrology (*ahkam-ı nücum*). In astrology, *Ahkam-ı Mehmed Çelebi* (Judgments of Mehmed Çelebi), an early seventeenth century work composed by the Münecimbaşı Mehmed b. Ali

al-Rumi (d.1630), seems to have enjoyed long-term popularity. Another important astrological work was composed by Mustafa Zeki al-Istanbuli, who was patronized by Şehid Ali Paşa in the early eighteenth century. Among Ali Paşa's clients was also the future Ottoman ambassador to the Versailles Yirmisekiz Mehmed Çelebi, who was a practicing chymist and ran the Imperial Foundry and the Imperial Mint. There was a vernacular revival of Islamic astronomy in the eighteenth century, where we find a Turkish rendition, with commentary, of *Zicc-i Uluğ Bey*. The aim of this work *Netayicü'l-Buluğ fî Şerh-i Zicc-i Uluğ* was to encourage the practice of astronomy, which, its author Abbas Vesim surmised, had been confined to theoretical training. A second important translation was Jamshid al-Kashi's *Süllemü's-Sema*, which dealt with reckoning the sizes and the distances of heavenly bodies. From the late seventeenth century onwards, we also find a number of Turkish ephemerides that were translated from Latin and French. Since ephemerides always placed planetary positions from the perspective of a terrestrial observer, they were readily put to use within the geocentric framework of Islamic *hey'et*. Although İbrahim Müteferrika, printer to Sultans Ahmed III and Mahmud I, presented a Cartesian defense of the "new astronomy" of Copernicus, the geocentric *hey'et* tradition seems to have continued throughout the eighteenth century, where the introduction of Copernicus to *medrese* manuals happened no earlier than the nineteenth century.

Geography and Cartography

Since geography and cartography were useful to sailors, administrators and military officers, most of the Ottoman geographical and cartographical literature was in Turkish. One of the most celebrated works was Piri Reis's *Kitab-ı Bahriye* (The Maritime Book), which included a number of important portolans. One of the most curious artifacts that Piri Reis left behind was his early sixteenth century map of the Americas.

The Turkish cartographic tradition merged Islamic-Ptolemaic cartography with the practice of portolan making. With Katip Çelebi, the famous polymath and translator of *Atlas Minor*, the cartographic projection methods of Gerhard Mercator also took a foothold among Ottoman geographers. The late seventeenth century was a turning point in the history of Ottoman geography and cartography, where three important books, Katip Çelebi's *Cihannüma*, Evliya Çelebi's *Seyahatname*, and Ebubekir Behram el-Dimaşki's *Terceme-i Atlas Maior* cultivated new approaches to both mathematical cartography and human geography with an unprecedented level of depth and breadth. Cartography was also one of the central concerns of the imperial printing press established in 1729, where the very first work to appear was a map of Iran – territories that the Ottoman Sultan claimed to have conquered. Over the eighteenth century, with the switch from a fortress-based understanding of territory to a border-based understanding of the land, geodesy became a permanent concern of the administrative elite.

Medicine and Natural History

Medicine always had a double career in Islam. As part science (*ilm*) and part art (*fenn*), the Ottoman medical marketplace was composed, much like Germany or Spain, of state-employed learned doctors and fee-collecting medical artisans. Formal medical training in Arabic was offered to doctors at the various hospitals and at the medical *medrese* of Süleyman I, where Ibn Sīnā's *Canon of Medicine* served as the backbone of medical training. However, from the fifteenth century onward, there was also a steady stream of Turkish language medical books that addressed the lay physician. One of the most important developments in seventeenth century Ottoman medicine was the emergence of the vernacular *tıbb-ı cedid* (new medicine), a movement that tried to merge the exact sciences, alchemy, and medicine under the same rubric inspired by Paracelsus and European authors who worked within a broadly

Paracelsian framework. Natural history, particularly accounts of the wondrous and the curious also attracted tremendous attention among Turkish readers. This is evident in the three independent translations of Qazwini's *Ajaib al-Makhlūqat wa Gharaib al-Mawjudat*. Natural history took on a more practical and borderline commercial tone after important drugs and herbs from the Americas became a fixture in the Ottoman markets. An Ottoman Grand Vizier, Mehmed Said Pasha, even wrote a polyglot lexicon of herbs and minerals in the eighteenth century.

Science of the Native Americans

Ubiratan D'Ambrosio

Graduate Program, UNIAN/Universidade
Anhanguera de São Paulo, São Paulo, SP, Brazil

It is commonly accepted practice to refer to the peoples and cultures established in the territory now called the Americas as Native Americans. When the expedition of Christopher Columbus reached the Caribbean Islands in 1492, they called the inhabitants "Indians." This is because of the Spaniards' mistaken view that they had arrived in Asia. Although Columbus himself never realized that he had reached another continent and kept referring to the lands as "Cipango," soon the conquerors realized that they were indeed in a continent as far from Asia as from Europe and dealing with a completely different culture. However, the early chroniclers used the denomination "West Indies," and up to now all the peoples and the cultures native to these newly encountered lands are called Indians.

The denomination "America" also came as the consequence of a fortuitous event. The navigator Amerigo Vespucci, who had visited and described practically the entire coast of the newly found lands, was consulted by German Cartographer Martin Waldseemüller, when he was writing the treatise *Cosmographiae Introductio*, a sort of revised version of Ptolemy's *Geography*. The cartographer, without a name for the new territories added to the original maps, coined the name "Americas" to honor the man who helped them to place these additions to the old maps. This vast amount of land stretched from about the North Pole to the South Pole, between Europe and Asia, roughly in the middle of the waters surrounding the known world. The peoples and cultures of this territory reached by Columbus, strangers to the conception of the world prevailing in the fifteenth century, are mostly referred to as "American Indians." The name Native Americans is not widely used.

The original occupation of the Americas (North, Central, and South) is uncertain.

The colonizers have claimed, an obvious political assertion, that the peoples in the Americas were immigrants who arrived from Asia through a glaciation of the Bering Strait no more than 20,000 years ago. Some theories claiming that these peoples are autochthonous were advanced in the early twentieth century, but they were disclaimed on the basis of a lack of scientific support. The best known of these theories is from the Argentinean anthropologist Florentino Ameghino (1854–1911). These claims recur frequently. The theory of a common origin for all of mankind, coming from the heights of Eastern Africa, is the most accepted version for the origin of humans in the Americas. They arrived in migratory fluxes through the Bering Strait, which does not exclude the possibility of ocean access, both through the Atlantic and the Pacific. There is mounting evidence of the presence of humans in these lands since 70000 BCE, but this evidence is very controversial. The most accepted versions place early findings of *Homo sapiens* at about 40000 BCE, without the presence of early hominids.

There is a considerable amount of material relating the impressions of the first Europeans who arrived in the Americas. The first one, the journal of Columbus, is the most important one, but others have also told of the enormous impression made by these peoples and lands on the Europeans. The chroniclers of the conquest reveal their surprise and failure in understanding such different cultures.

Most of the attempts to interpret scientific knowledge in the Americas prior to the arrival of Europeans are limited to a description of what was seen. Buildings, roads, agricultural fields, and artifacts are always listed as evidence of knowledge. Their meaning and cultural context are problematic. An example is the *quipu*, a collection of colored strings with knots, taken as a form of abacus. We now understand these are a very elaborate form of register, both qualitative and quantitative. Also, the wheel appears frequently in pre-Columbian cultures but without the uses so well known in the history of Europe and Asia.

There is a reasonable amount of literature on science and technology in the Americas in the pre-Columbian era written by anthropologists and psychologists. To relate this to the work of historians and philosophers of science and technology is an important step toward a broader understanding of the nature of science and technology and their places in societies. This asks for a clear recognition of the dynamic character of knowledge, from its generation through its organization, both intellectual and social, and through its diffusion. Although these aspects are studied in disciplines such as cognition, epistemology, history, politics, and education, it is practically impossible to understand and explain knowledge in such a fragmented way. This is an important step toward recognizing different modes of thought which lead to different forms of science, which we may call *ethnosciences*.

Research on the status of knowledge in the Americas in the pre-Columbian period uses methodological instruments and an intellectual posture of classifying it according to accepted, European, views of science. The underlying epistemology is dictated by current scholarship. Thus, research focuses on ethnoastronomy, ethnobotany, ethnochemistry, and so on. The “ethno” prefix stands for “the astronomy of the Aztecs,” for example. This reductionist approach does not take into account the meaning of “astronomy” for the Aztecs. This is true for every science. A special situation occurs in the recognition of an ethnomethodology in different cultures. Researchers in this field rely on ethnography, the use of direct observation, and extended field research. This produces a naturalistic description of peoples and their culture, uncovering codes, symbols, and categories of analysis which these peoples use to conceptualize, explain, understand, and interpret reality. The generation of these instruments is the essence of studies in cognition and culture. We are thus led to look into the history of science in a broader context, so as to incorporate other possible forms of knowledge, interpretation, and explanation, to deal with nature and natural phenomena.

Generation of knowledge goes on in different environmental settings, according to a

multiplicity of stimuli. Practices are created by individuals in response to their immediate needs, motivation, and curiosity, and thus generated, they are intellectually organized as knowledge. A communication system of codes and symbols allows this knowledge to be transmitted informally throughout society and socially organized before it is diffused through education. Its growth into more and deeper knowledge is now a response to further needs and curiosity. These new responses (the *hows* and the *whys*) are incorporated in the pool of common knowledge which keeps a group of individuals together and operational. This is usually called *culture*.

Cultural forms, such as language, eating and drinking preferences, musical and bodily expression, mathematical practices, religious feelings, familial hierarchy and structure, dressing, and behavior patterns, are thus diversified. A larger community is partitioned into several smaller ones, from individuals and their immediate kin to communities and societies, each with distinct cultural variants. The multiplicity of cultural factors is essentially responsible for the dynamic process of the production of new forms of thought and of more sophisticated expressions of the ingenuity of individuals and societies in satisfying their needs of survival and of transcendence. This is the process we call *cultural dynamics*.

A theory of culture is thus the result of analyzing the intellectual evolution of humankind, focusing on the search for different practices and intellectual tools for explaining, understanding, learning about, and managing their natural and sociocultural environment. In “explaining, understanding, learning about, and managing,” we recognize the Greek root *mathema*. And a natural and sociocultural environment is well expressed by the prefix *ethno*. Thus we have coined the word *ethnomathematics* to describe the mathematical practices of the day-to-day lives of preliterate cultures. In a broader sense, *ethnomathematics* is a research program in the history and philosophy of mathematics, with pedagogical implications.

Much has been said about the universality of knowledge, in particular of scientific knowledge. This concept of universality becomes harder to

sustain as recent research shows evidence of practices, such as health care and tool use, which are typically scientific, and methodological practices, such as observing, counting, ordering, sorting, measuring, and weighing, all performed in distinctive ways in different cultural environments. This has encouraged further studies on the evolution of scientific concepts and practices within a cultural and anthropological framework. We feel this has been done only to a very limited, and we might say very timid, extent. Indeed, universality of knowledge, more specifically of scientific knowledge, is a fabrication of the colonial ideology.

A new historiography reestablishing authentic universality is needed. There is some agreement about this in several areas of knowledge, but the history of science seems to be immune to this movement. Indeed, the tone of some reviews of recent books and papers in the history of science, in particular mathematics, focusing on this form of redeeming cultural history or proposing a non-Eurocentric view, is discouraging and, sometimes, contemptuous. It is well recognized that the best strategy for hegemony is the suppression of historicity of the subordinates. Here is an example from the history of science: the first nonreligious book published in the New World was Juan Diez Freyle's *Treatise Dealing with the Arithmetic of the Aztecs* in 1557. Less than a century later, this book had lost its appeal and became completely lost, along with pre-Columbian arithmetic. Freyle's book was ignored and replaced by the arithmetic of the Spaniards.

The suppression of the history of a people involves the removal of all traces of structured knowledge, labeling all forms of knowledge as "popular wisdom," superstition, and folklore.

Early Cultures in the Americas

The early cultures in the Americas are distinct, according to broad ranges of latitude. The peoples in the icy northern regions developed into a culture generally known as Inuit, or Eskimos. Those in the fertile northern prairies and woods

of what is now the United States and Canada, ranging from the Pacific to the Atlantic, were identified under the generic name of "Indians," organized into several distinct nations. Those in the more desert regions neighboring the Rio Grande were distinct nations with a distinguishable urban organization and rather unique architectural forms. South of the Rio Grande, in the highlands of Mexico and Central and South America, there are peoples with cultural styles of a rather different nature. These peoples are now called Aztecs in the region around what is now called the Ciudad de Mexico, Mayas in the Central American jungles, mainly southern Mexico and Guatemala, and Incas, spread throughout the mountainous region called the Andes, from the northern part of South America to the northern part of Chile. Aztecs, Mayas, and Incas are called the "high civilizations" of the Americas. In the "lower lands" – coastal areas, the Amazon Basin and subsidiary basins to the South, and much of the territory east of the Andes – other cultures flourished in a very different style. Apart from the high civilizations, and not mentioning those cultures north of the Rio Grande, we have to mention as best organized those located in the Island of Marajo (in the mouth of the Amazon River), with a considerably developed pottery; the agriculturalist Araucanians in the Southern part of South America; and the Guaranis, the latest major group to organize themselves in an agricultural economy, in central South America.

The Aztecs are distinguished by a monumental religious architecture, with abundant pyramids with precise designs to accommodate astronomical data. The Aztec calendar reveals these achievements. Sculpture was at a level of sophistication comparable to civilizations in the Old World. Commerce was developed and practiced in large fairs. They used numbers and measures but had no commerce by weight. The Aztecs were skilled workers in ceramics and in metals (gold, silver, copper, tin, and bronze). They had hieroglyphic writing, using colors which endure to the present day, literature, and a school system.

The Mayas had distinctive urbanization styles. Stone pyramids, temples, and palaces, decorated

with very elaborate sculptures, were religious centers, and the population was spread in the surrounding jungles. These centers appear to have been temporary. One hypothesis is that they were abandoned as new ones became ready – another possibility is that the mobility was the result of destruction by wars. These peoples had a very advanced astronomy, with data comparable to those available to the Europeans. From the sixth century, they had developed the zero and positional number system, thus producing an advanced arithmetic. They also had a pictorial writing system which was not recognized as such by Europeans. Some early translators relied on reports of books and documents without recognizing this as reading.

Among the classics of their literature, we have the elaborated description of the origins of the world and men, the *Popol Vuh*, a book written in the mid-sixteenth century, in Central America. The book describes, simultaneously, the myths of origin, the history of kings, and the peoples of the region, as well as the catastrophe of the Spanish conquest.

Also very important is the book of natural phenomena, the *Chilam Balam*. It describes a myth of origins, similar to the *Popol Vuh*, when gods of the underworld kept the universe captive. Also of great importance is the war drama *Rabinal Achi*, a piece showing the existence of a form of ritual theater. It is typical of the post-Classical period of the Maya civilization, from the tenth to the fifteenth centuries. Maya cultures developed a series of artistic expressions which included dancing, theater, music, and literature.

The third high civilization, known as the Incas, took the name after their monarch. The Inca was the highest religious, civilian, and military authority. Although succession was by blood, the successor was not necessarily the eldest son. Like the Aztecs, the religion of the Incas was focused on the divinity of the sun, and human sacrifices were common. The architecture of the Incas was of a varied nature. Visitors still marvel at what is called cyclopic architecture, buildings and palaces constructed using enormous stones, as in Machu Picchu, Peru.

The early history of these cultures reveals a great dispersion of nomadic groups, with an economy of hunters and collectors. In general, in all of the Americas, animal domestication was modest. In Mexico, turkeys were domesticated; in Peru, the llama and the alpaca, as pack animals and for textiles, were also domesticated, as were dogs and some rodents. Some tribes farmed turtles, some bees and birds, mainly parakeets and parrots. Fish from the coasts of Peru were consumed in the high altitudes, transported and preserved through a sophisticated system of utilization of natural ice.

Agriculture was much more developed. About 6000 BCE, we see evidence of the domestication of plants, mainly in the northern region (north of Mexico and southeast United States), among them squash, cotton, and several species of beans. The important development of maize (*Zea mays*) opens up a new era in the development of agriculture and the settlement of people in larger regions, which characterizes the urbanization period. There is much controversy about when this occurred. A recent academic argument about the occurrence of maize in Panama, 5000 versus 3000 BCE, is more important for revealing the search for a new historiography for science and technology in pre-Columbian Americas than for the dating question itself.

Intensive Agriculture and Urbanization

Up to the beginning of the Christian era, we see the formation of agricultural cultures. They developed different techniques, using fire, intensive irrigation, fertilization, and terrace agriculture. Agriculture was the main subsistence form and the determinant of the political struggles and the development of economy.

A special and unique type of building, characterized by yards built with stone walls, was recently located in the center of a village in La Puntilla, Peru. There are indications that these buildings, dating about 2,000 years ago, were for centralized work and not for ceremonies. Other findings, such as finding manufactured products in domestic units, reveal an organized

structure for distribution of the production, suggesting the existence of a dominant class controlling production. An intense craftsmanship, which included making andesite and obsidian tools, manufacturing ornaments of marine shells, weaving, and spinning, and agricultural processing tasks are present. It is also notable that some of the raw material used in the crafts, as, for example, spondylus shells, are not local but brought from distant lands, probably the coastline of Ecuador.

As we advance in time, around the second millennium AD, we see the development of a variety of urban styles: the weaving of cotton and wool; pottery and ceramics; statuary; metallurgy, especially work in gold; ritual decoration; and architecture. We notice the development of several forms of pyramids, possibly evolving from the common funerary mounds, and other forms of religious architecture. Ceremonial dressing is varied, with feathers, plants, animals, painting, and bright colors. The period also reveals, probably as a consequence of the permanent struggle for land, the development of a variety of languages, with more than 2,000 distinct languages or dialects. In the lower lands, there is considerable development of agriculture, mainly manioc or cassava (*Manihot utilissima*) and sweet potatoes (*Ipomoea batatas*).

There is also evidence of an intense coastal commerce. Indeed, navigation in the Pacific seems to be highly developed among the Andean cultures. There is recent evidence of Japanese arrivals in what is now Ecuador about 3000 BCE. Also, there is a possibility of commercial exchanges between China and South America in the first century AD, and contacts between Mexico and Africa in the first millennium are most probable. There are no doubts about the practice of considerably advanced navigation among the high civilizations.

There is much controversy about the development of a written/pictorial form of language. As mentioned above, recent findings reveal a written language among the Mayas. They also developed calculations, especially for astronomical and commercial purposes, with a sophisticated

vigesimal (base 60) system. The register of historical and statistical data was rather sophisticated, as with the surprisingly powerful *quipus* among the Incas. Calculating devices, such as the *yupana* (see <http://www.quipus.it/english/Andean%20Calculators.pdf> for a detailed discussion of Andean calculators), reveal theoretical approaches as yet not sufficiently studied. We are just beginning to recognize the formal knowledge – logic, mathematics, philosophy – possessed by these cultures.

Colonial discourse was absolutely biased in saying that the American peoples were not highly developed. Agriculture was developed in Asia in the eighth millennium BCE, while there is evidence that it was developed in Mexico only in the fifth millennium BCE. Ceramics and pottery are seen in Asia about 6000 BCE, while they appear in 3000 BCE in the northeast of South America. Proto-literacy is recognized in Mesopotamia about 3300 BCE but in Mesoamerica only about 800 BCE. Urban cultures are seen in Egypt and Mesopotamia using writing and bronze about 2800 BCE, while limited writing and metallurgy are identified in urban complexes of Mexico and Peru only in the beginning of the Christian era.

What was going on in the centuries preceding the arrival of Columbus was a political process very similar to that which took place in Europe during the Middle Ages, when principalities and other smaller domains were uniting into larger organizations such as kingdoms and nations. The Spanish conquerors were able to take advantage of the local conflicts in destroying the emergent power elites and replacing them with the power of the conqueror, based on a well-balanced state/church structure controlling the means of production. Although effective production was in the hands of natives, the conqueror assumed the role of the native monarchy in controlling the centralized system. Even now, production is, to a great extent, done by impoverished natives. A 1950 study showed that in Bolivia, about 4,000 native communities were responsible for about 25 % of the agricultural production. The conqueror succeeded in deepening these conflicts. As a result, today different cultures, even

different tribes, do not recognize their common history. In the lower lands, east of the Andes and the Amazon Basin and subsidiary basins in the south, and mainly in the Atlantic coast, the strategy was no different.

As we have said before, knowledge is generated as a permanent activity of human beings. It is carried out by individuals and groups of individuals in different environmental settings, according to a multiplicity of stimuli. Among the several stimuli, we have to consider cultural encounters and mutual exposition of different modes of thought. In the evolution of cultural forms subjected to mutual exposition, the possibilities are, first, an absolute domination of one form, either leaving the others in the state of latency or leading them to an eventual total elimination and, second, allowing coevolution, which eventually leads to new cultural forms. This second possibility occurs in systems which are tolerant of the different, of the stranger. Thus, our analysis of the formation of scientific knowledge and the development of technology among the civilizations of Latin America necessarily goes through an analysis of the occupation of territory and the development of means of production.

To conceptualize modes or styles of development is crucial for better understanding of the evolution of native knowledge systems, in particular science, in the Americas. The Latin America Economic Commission of the United Nations proposed, in the 1960s, the conceptual basis for development. Development is understood as a strategy resulting from political agreement or group alliances, with the objective of reaching a common goal. Thus a model of development is the result of the power structure and of the social conflicts resulting of the prevalent forms of capital accumulation and distribution of richness. These are based on a complex of historical circumstances that go back to the conquest, colonial period, and the early decades of independence. These internal and external conjunctures are in conflict with the values intrinsic to the cultures. To understand the native knowledge systems, a new historiography is needed, anchored in the concept of models of development.

Sde Srid Sangs Rgyas Rgya Mtsho

Zhen Yan

Sde srid sangs rgyas rgya mtsho is a famous Tibetan politician and naturalist. Nicknamed Sde pa, he was born in the water snake year of the 11th Rab-byung (Tibetan calendar, 1653) in the Northern suburb of Lhasa, Tibet. His father's name was A sug, and his mother, Bu khrid rgyal mo.

Politically, he was a person who inspired controversy, either commendatory or derogatory. But he was a great naturalist. His contributions

in Tibetan medicine greatly promoted the development of this branch of science during his time.

Since he was a very talented child, he came to the attention of the fifth Dalai Lama Ngag dbang blo bzang rgya mtsho, who paid special attention to his education. He was summoned to the Dalai Lama's Potala palace to learn the classics of the Buddhism, apparent and esoteric sects. He had many tutors. 'Dar pa was the tutor for languages, Sanskrit and calendar-mathematics; Rong ge ngag dbang for astrology; Lhun sdings rnam rgyal rdo rje for allegorical trees, body measurement, and esoteric recipes. Thus, he became a versatile scholar with a high reputation.

The fifth Dalai Lama assigned him to the post of Sde srid (the Regent or Prime Minister), which was like giving wings to a tiger. During his tenure as Sde srid, he used any leisure time to take advantage of having access to many rare documents and materials available in the palace. He was very erudite in natural sciences, including medical science. His works, for instance *Baidurya dkar po* (White Lapislazuli), and *Baidurya ser po* (Yellow Lapislazuli), deal with the calendar, mathematical sciences, and religion. However, his achievements in medical science will be emphasized here.

First, he studied *Rgyud bzhi*, the most important ancient Tibetan medical canon. Due to his political position, he had contact with many famous physicians. He admired Dar mo sman rams pa blo bzang chos grags very much, claiming that he was very erudite and had many esoteric effective recipes. He learnt from the different revised and annotated editions produced by the new Gyu thog yon tan mgon po, the greatest ancient Tibetan medical figure. He also made his own annotations and revisions on *Rgyud bzhi*.

Rgyud bzhi, authored by Gyu thog rnying ma yon tan mgon po, or the old Gyu thog, is written in archaic Tibetan language, which is hard to read; moreover, it is written in the form of an ancient Sloka-poet form, which is difficult to comprehend. Based on his experiences and practice, he adopted all the merits from different schools and physicians, discarded the erroneous and extracted the essence. With all these elements as a basis, he wrote a new detailed commentary

on *Rgyud bzhi* with the title *Gso ba rig pa'i bstan bcos sman bla'i dgongs rgyan rgyud bzhi'i gsal byed baidurya sngon po'i malli ka zhes bya ba bzhugs so* (The Medicine Buddha's Decorated Four Tantras Annotation, The Blue Lapis Lazuli), or *Baidurya sngon po* for short. The book, twice as long as the original *Rgyud bzhi*, was finished in 1687. Since this is a comprehensive text embodying the merits of all scholars with refined contents, easy to read and understand, many scholars appreciate it. It has become the standard commentary on *Rgyud bzhi* and is treated as a compulsory text for learning it.

Sangs rgyas rgya mtsho also wrote many other medical books. Among them, *Gso rig sman gyi khog 'bugs* (History of Tibetan Medicine) is the most famous and important. Its full title is *Dpal ldan gso ba rig pa'i khog 'bugs legs bshad baidurya'i me long drang srong dgyes pa'i dga' ston bzhugs so* (General Introduction to Medicine, The Happy Feast of Immortals). This is by far the most authoritative text in Tibetan medical history. Furthermore, he was not satisfied with *Baidurya sngon po* only, so he wrote another book, *Man ngag rgyud lhan thabs* (Supplement to Secret Tantra) to make up for the deficiencies of the original classic. His medical works number over 20.

Sangs rgyas rgya mtsho was very enthusiastic about education in Tibetan medicine, paying attention to the training of successors. Right after the enthronement of the fifth Dalai Lama, the spiritual leader ordered that a medical school be established at 'Bras spungs Monastery in the Western suburbs of Lhasa, enrolling young people from the region with *Rgyud bzhi* as its main curriculum. Moreover, the Dalai Lama also instructed the restoration of the class in Xigatze to continue its training of Tibetan medical workers. The title of the class was changed to *Shen xian yun ji si* or *Drang srong 'dus pa'i gling* (Monastery for Aggregation of Immortals). Again, *Rgyud bzhi* was its main curriculum. Unfortunately, the latter was suspended upon the death of the Dalai Lama.

Several years later, Sangs rgyas rgya mtsho selected the site of Lcag po ri (Iron Hill) just opposite the Potala Palace to set up another

medical school in line with the will of the late Dalai Lama. The curriculum included, in addition to *Rgyud bzhi*, other books such as *Zeng bu si bu yi dian mi jue ben ji* (Supplements to Collection of Man ngag rgyud) and *Cao yao mi fang* (Secret Herbal Formulary). Practice was also summarized. For instance, herbs were collected each year in the mountains, and students were encouraged to recognize various medicinal herbs and gain a better understanding of nature.

Sangs rgyas rgya mtsho set up an advanced medical class within the Potala Palace, and famous physicians were invited to teach. To improve teaching efficiency, Sangs rgyas rgya mtsho designed and produced a set of intuitive teaching tools, hanging painting scrolls, called *Sman thang* in the Tibetan language.

Under the auspices of Sangs rgyas rgya mtsho, the drawing of a series of *Sman thangs* was initiated. Sangs rgyas rgya mtsho used his *Baidurya sngon po* as a basis for the paintings and, by 1688, a series of 60 paintings had been completed. But, Sangs rgyas rgya mtsho was not satisfied, and he added more detail of pulse feeling, urine analysis and ► [moxibustion](#), and sketching the actual samples of herbs collected from places throughout the region. Thus, a complete set of 79 paintings was finally produced in 1704.

As an epochal event in the history of Tibetan medicine, Tibetan medical paintings include all aspects of the medical field, such as the origin of medicine, fundamental theory, physiology, anatomy, etiology, pathology, therapeutic methods, surgical instruments, symptoms of all clinical aspects, diagnostics, materia medica and prognosis, and medical ethics as well which is not only the first of its kind but also the only example in the history of world medicine. This popularized medical knowledge with intuitive education, playing a very active role in the spreading and popularization of Tibetan medicine. It is a rare valuable historical relic with very high value that has attracted much attention around the world.

Sangs rgyas rgya mtsho was a great medical man. He made substantial and distinguished contributions to the development of Tibetan medicine. Unfortunately, his political notions clashed with other politicians, and the relationship among

them deteriorated after the death of the fifth Dalai Lama. He was assassinated by his enemy and died a premature death at the age of 53.

Seafaring

Robert Bednarik

International Federation of Rock Art Organizations (IFRAO), Caulfield South, Australia

When humans began to cross sea barriers, they demonstrated what they were capable of by harnessing nature. This may have been the most consequential single achievement in human history, because it marked the advent of the domestication of natural systems – the evolution of technologies that harness such energies as wind, wave action, current and buoyancy. The importance of this is not so much in the expanded ability of colonization or the introduction of “assisted locomotion,” but in the cybernetic feedback derived from the conscious manipulation of natural systems and its impact on the cognitive and intellectual development of hominins. From an archaeo-technological perspective, early maritime navigational ability provides a more accurate determination of maximal technological capability than any other available evidence – rather in the same way as space travel does today. Hence there are several good reasons

to take a special interest in how, when, and where seafaring began.

No physical evidence of Pleistocene seafaring has ever been reported, nor have we any credible depictions of watercraft in the rock art or portable art of the Ice Age. Direct archaeological evidence of navigation peters out between 8,000 and possibly 10,500 years ago (Bednarik, 1997), consisting of Mesolithic paddles from Holmgaard (Denmark) and Star Carr (England); a worked reindeer antler that may have been a rib of a skin boat in the Ahrensburgian of Husum (Germany); and the somewhat younger canoes and dugouts from Pesse (Holland, $8,265 \pm 275$ carbon years), Noyen-sur-Seine (France, $7,960 \pm 100$ carbon years), and Lystrup 1 (Denmark, $6,110 \pm 100$ carbon years) (Arnold, 1966; Bednarik & Kuckenburger, 1999; Clark, 1971; Ellmers, 1980; McGrail, 1987, 1991; Zeist, 1957). Watercraft and paddles of the late first half of the Holocene are also known from two Japanese sites (Aikens & Higuchi, 1982, p. 124; Ikawa-Smith, 1986). Bitumen-covered wooden slabs thought to have been part of boats, about 7,000 years old, were found in the Kuwaiti desert, in a stone building at the site As-Subiyah. The subsequent development of watercraft in the Middle East and later elsewhere is not considered here; it does not refer to the beginnings of seafaring.

Indirect evidence of maritime travel occurs in a variety of forms: as human occupation evidence, human remains, rock art, or exotic materials found in the archaeology of islands or continents that were never connected to another landmass since humans first appeared. For instance, such evidence can be in the form of insular obsidian on the mainland, as that from Frachthi Cave in Greece, 11,000 years old (Perlès, 1979; Renfrew & Aspinall, 1990). Much earlier sea crossing and island colonization is indicated by Mousterian tools on Kefallinía, west of Greece (Kavvadias, 1984; Warner & Bednarik, 1996), and by the presence of Clactonian-like stone tools and human remains in Middle Pleistocene sediments on Sardinia (Bini et al., 1993; Ginesu et al., 2003; Martini, 1992). Crete was also occupied during Paleolithic

times, as indicated by human remains of a modern specimen with preserved archaic features (Facchini & Giusberti, 1992, p. 200) and extensive deposits of Lower and Middle Paleolithic stone tools (Mortensen, 2008; Strasser et al., 2010, 2011). In Japan, Paleolithic seafaring is demonstrated by the remains of four humans at Okinawa (Baba, 1998) and by transported obsidian at Kozushima (Anderson, 1987), and in North America by the two femora fragments and one humerus from Arlington Springs on Santa Rosa Island (reportedly 13,000 years old). However, in comparison to the seafaring evidence in the region of Indonesia and Australia, most such finds from Europe and elsewhere are comparatively recent. The only evidence of a Lower Paleolithic island occupation outside that region is that from Sardinia, on the order of 300,000 years old. It seems also probable that the first colonizers of Europe crossed the Strait of Gibraltar, even though secure evidence for this is lacking (Bednarik, 1999a).

In March 1957, Dutch researcher Theodor Verhoeven found stone implements eroding from a fossiliferous deposit at the site Ola Bula in Flores, a geologically recent island of Indonesia (Verhoeven, 1968, p. 400). A leading archaeologist, Henri Breuil, recognized among these finds a number of typical Lower Paleolithic stone implements (Verhoeven, 1958, p. 265). In mid-1963, Verhoeven succeeded in demonstrating by excavation the contemporaneity of Flores artifacts with fossil remains of *Stegodonts* (extinct elephants) at a second, nearby site, Boa Leza. Johannes Maringer, an archaeologist of the Anthropos Institute, Germany, joined him in 1968, and the two excavated together at Boa Leza, Mata Menge, and Lembah Menge. The three sites occur within easy walking distance and are all exposures of a geological stratum rich in fossil remains and stone tools (Maringer, 1978; Maringer & Verhoeven, 1970a, b, c, 1972, 1975, 1977). This deposit is overlain by a series of rock facies up to 120-m thick, so there can be no question about the great antiquity of this presence of humans on an island that has never been connected to any other landmass. Initially this evidence was estimated to be up to

Seafaring,

Fig. 1 Stegodont remains and stone tools in solid siltstone deposit, ca. 840,000 years old, Boa Leza, Flores (Photo by author)

830,000 years old, based on the geology, paleontology, and the presence of tektites. (Tektites are glassy objects that are thought by most scientists today to be melt products of terrestrial rocks formed by hypervelocity impacts of large, extra-terrestrial objects.) (Koenigswald & Ghosh, 1973) Subsequent paleomagnetic analyses at Mata Menge (Bednarik, 1995; Sondaar et al., 1994) suggested that the Matuyama-Brunhes reversal to normal polarity (780,000 BP) occurs just below the fossiliferous stratum. Later applications of fission-track analysis of zircons yielded datings of stone tool-bearing sediments from Boa Leza, Mata Menge, Koba Tuwa, and Ngamapa, and all fell between 750,000 and 850,000 years BP (Morwood et al., 1999) (Fig. 1).

It thus seems soundly demonstrated that *Homo erectus*, currently the only available hominin candidate, was sufficiently well established on the island of Flores towards the end of the Early Pleistocene to leave behind numerous major deposits of stone tools. Flores is separated from Bali, the furthest extension of the Asian mainland during the Pleistocene (at times of low sea level), by two other islands, Lombok and Sumbawa (as well as several smaller islands which may have been connected to the larger ones at times of lower sea level), and the lack of any former land bridge between Bali and Lombok was initially recognized by Wallace (1890). While this is based primarily on biogeographical observations, it is supported by the continuing uplift in the “inner arc” of the Indonesian archipelago, which

amounts to at least several 100 m over the past million years in this tectonically active subduction zone. Despite the rich mainland fauna of both extant and fossil terrestrial eutherians (placental mammals) that can be found as far east as Bali, few of them ever reached the islands of Nusa Tenggara, or southern Wallacea (Bednarik & Kuckenburg, 1999, pp. 108–109). Some, such as the dog, pig, and macaque, were probably carried by humans, while small mammals, mostly Muridae (mice, rats, voles, and relatives), probably crossed on floating vegetation (Diamond, 1977). Elephants, however, swam to many of the islands of Wallacea (Bednarik, 1999b; Glover, 1969; Hooijer, 1957; Verhoeven, 1958, 1964) and the Philippines (Koenigswald, 1949), where they underwent speciation and dwarfism. Elephants are superb long-distance swimmers, able to swim 48 km at sea and at a speed of 2.7 km/h (Johnson, 1980). Hominins, however, lacked the trunks and swimming ability of elephants. Even deer, hippos, tapirs, and pigs, four of the most capable terrestrial long-distance swimmers, never colonized Wallacea unaided (Fig. 2).

In 1998, Australian Bednarik demonstrated the contemporaneity of human occupation with a Stegodont-dominated Middle Pleistocene fauna in West Timor (Bednarik, 1999b). His fieldwork in Timor and Roti has involved several Pleistocene sites in the island’s western half (East Timor having become politically stable only recently), focusing on the Weaiwe valley near Atambua.

Seafaring, Fig. 2 Map of southern Wallacea (Nusa Tenggara), Indonesia. The presumed dividing line between the Eurasian and Australian continental plates is shown *dotted*, and Wallace's biogeographical line is

between Bali and Lombok. The *squares* indicate known hominin occupation sites of the Early and Middle Pleistocene

There, a sequence of Pleistocene sediments occurs above estuarine clay deposits containing an abundance of marine shells and snails. This demonstrates an uplift of well over 300 m since they were formed. The Weaiwe Formation, a Pleistocene conglomerate, has yielded remains of *Stegodontidae* from six sites now (Bednarik & Kuckenbug, 1999), and evidence of human presence in the fossiliferous stratum occurs at two, Motaan and To'os (Bednarik, 1999b). At the time of its formation, the Pleistocene occupation layer was located close to sea level, which could itself have been much lower at the time.

All of the islands from Bali to Timor and Roti are well visible from the shores of departure, but once the Middle Pleistocene mariners had settled Timor, they could travel no further. The shores of Australia have never been visible from Timor, at any sea level, and it appears that the lack of visual contact prevented the human colonization of Australia for many hundreds of millennia. The initial landfall in Australia is presently thought to have occurred about 40,000–60,000 years ago. By that time, it appears, the Ice Age seafarers had acquired sufficient experience to venture into the unknown, to depart without the certainty of seeing their destination. It would have been known to them since time immemorial that there was a large landmass to the south. They could have predicted this from plumes of smoke occasionally rising from grassfires in Australia, from cumulus clouds regularly forming over the land, and from the movements of waves, currents,

migratory birds, and turtles. But there is a great leap from merely predicting the existence of land to having the courage of embarking on a journey of no return to an unseen shore.

A good deal of evidence from about 33,000 to 27,000 years ago indicates that many islands near northern Australia had been settled by that time. These amazing seafarers, with their still essentially Middle Paleolithic technology, undertook lengthy journeys to in some cases very small target landmasses (Bednarik, 1997). Most of these islands could not have been sighted until a raft reached their proximity; this is the case with the Monte Bello Islands (100 km from Australia), Gebe Island (west of New Guinea), New Ireland (east of New Guinea), and Buka Island (180 km from New Ireland). It thus seems very probable that the maritime competence of the much later Polynesians was the ultimate outcome of a process that began almost a million years ago.

The complete lack of any direct physical evidence of maritime technology from the entire Pleistocene renders it pointless to speculate about the circumstances of these endeavors without additional information. No sustained replicating experimentation of archaeology had been conducted in relation to this subject before 1996. Since then, the First Mariners Project (<http://mc2.vicnet.net.au/home/mariners/web/mariners.html>) led by Bednarik has set out to determine the most likely means employed by *Homo erectus* in crossing Lombok Strait >840,000 years ago and the most likely

Seafaring,

circumstances of first landfall by *Homo sapiens* in Australia and elsewhere. The project investigates all demonstrated human sea crossings of the Pleistocene and plans to replicate many of them. Archaeologically derived knowledge about the technology of the periods in question, particularly in stone tool knapping and wood and bone working, serves as a reference source for these projects (Bednarik, 1997, 1999b, 2001a). Some aspects of relevant material use can be replicated precisely on the basis of form of, and work markings on, archaeological finds, as, for instance, Middle Paleolithic bone harpoons or Lower Paleolithic wooden artifacts. Others must be determined according to systematically derived probability estimates based on experimentation. Expeditions endeavor to create authentic conditions for the construction of a series of primitive vessels and their sailing across the sea barriers in question. This involves, for instance, the use of appropriate stone tool replicas in felling and working bamboo and in constructing and sailing the rafts. Hundreds of issues of technology need to be addressed, including the means of carrying freshwater, of fishing at sea, of locating sources of stone tool materials for raft construction, issues of maritime design, and the procuring, selection, treatment, and utilization of materials for the construction of vessels and equipment (Fig. 3).

The first full-size experimental vessel was launched at Oeseli in southern Roti in early

1998 and sailed for sea trials with a crew of 11 (Bednarik & Kuckenburger, 1999). Some aspects of this 23-m-long, ocean-going bamboo raft of about 15 t plus cargo were judged to be unsuitable and the vessel was beached for destructive sampling and material testing. A radically different, simpler design led to an 18-m bamboo raft of only 2.8 t. It travelled with a crew of five men from Kupang to Darwin in December 1998, sailing part of the 1,000-km journey under extreme conditions (Bednarik, 1999b; Bednarik et al., 1999). In March 1999, a simple 11-m bamboo platform set out from the easternmost point of Bali to attempt a crossing of Lombok Strait. It was forced north by strong seas and the attempt was abandoned. But by the end of that year, a similar, 12-m-long simple platform of bamboo, lacking any sail or means of steering, was being built for a second attempt. This vessel was as rudimentary as a raft can possibly be, weighing only 1,080 kg. It crossed Lombok Strait successfully with a crew of 12 men in January 2000. The experiment showed how even a treacherous stretch of sea such as Lombok Strait could be crossed with purely Lower Paleolithic means (Bednarik, 2001b). Similarly, the 12-m *Rangki Papa* ("Father of all Rafts," in the local dialect) succeeded with a crew of 12 in October 2004 in crossing Sape Strait, which separates Sumbawa from Komodo and Flores. In that experiment, filmed by *National Geographic*, the assembly of the 970-kg bamboo vessel took only 4 days. Four years later, a similarly sized raft, this time constructed from green bamboo but

Seafaring, Fig. 4 Use of a firebox on a Paleolithic vessel, the fire having been lit by traditional method (Photo by author)

Seafaring, Fig. 5 A dorado fish just harpooned with a Middle Paleolithic weapon is about to be gutted with a stone flake (Photo by author)

performing outstandingly well, succeeded in crossing the treacherous currents between Lombok and Sumbawa with ten men, as filmed by *BBC*. The experiments in the Mediterranean had commenced earlier, in September 1999, on the coast of Morocco, where two prototype rafts were constructed entirely with Lower Paleolithic stone implement replicas and then taken for sea trials. One of these vessels, a pontoon-type raft, was made of cane, the other of inflated animal skins (Bednarik, 2001a) (Figs. 4 and 5).

The primary purpose of these experiments is to examine each of the many variables involved in Pleistocene seafaring quantitatively, to create the conditions for constructing multiple scenarios within a realistic framework of probability. In this procedure, the confidence that the most probable scenario can convincingly be identified is a function of the variables or determinants accounted for satisfactorily. Therefore, numerous experiments are essential, and all need to be conducted under controlled conditions. While the most sensible, economic, or logical course of action is not necessarily the one always taken by hominin mariners, there are several arbitrary limiting factors. For instance, these journeys had

much to do with survival, and we can reasonably assume that they were on the very limits of the technologically possible at the times in question (Bednarik, 1999c). The most probable scenarios can then be tested by reference to known parameters of technological competence at the time in question. These are derived from the archaeological research forming part of the overall project. This would seem to be the only scientific method available to us to generate informed and plausible explanations for the very early maritime feats of hominins.

Seafaring in the Polynesian Outliers

Richard Feinberg and Marianne George

Observers, for many years, viewed indigenous Pacific Islands seafaring as a vanishing art, largely confined to the Central Carolinian atolls of Micronesia. Yet, in a number of small, remote Polynesian communities, traditional vessels and knowledge of how to use them are an active, ongoing concern. Our awareness of these systems of knowledge and practice is preserved in works on Ontong Java and Nukumanu (Feinberg, 1995; Haddon & Hornell, 1975 [1936–1938]; Sarfert & Damm, 1929), Taumako (Davenport, 1962, 1964, 1968; George, 1998, 1999, n.d.; Lewis, 1972; Vaka Taumako Project, 1997, 1999), and Anuta (Feinberg, 1988, 1991). Important information also is presented on Kapingamarangi by Lieber (1994) and on Tikopia in Firth's voluminous writings.

Generalizations about these “Polynesian outliers” are difficult. They range from communities like Sikaiana (Donner, 1995), where sailing canoes have been entirely abandoned, to such isolated specks of land as Taumako and Anuta, where traditional equipment and techniques remain in use or are remembered to a remarkable degree. Even in precontact days, the Polynesian outliers incorporated a good deal of diversity.

On Ontong Java, Nukumanu, Takuu, and Nukuria, vessels as well as sailing and wayfinding techniques closely resembled those of Micronesia; on Tikopia and Anuta, maritime technology and practice have been closer to the standards typical of Polynesia. Meanwhile, the impressive seafaring technology of Taumako (Duff Islands) and the Polynesian Reef Islands of the eastern Solomons combines elements known from Eastern Polynesia, the central outlier atolls, and Micronesia (Fig. 1).

Canoe Construction and Design

Hull design in the central and northern Polynesian outlier atolls resembles that reported for the Micronesian Caroline and Marshall Islands. This is particularly evident in the voyaging canoes that have been described for Takuu (Haddon & Hornell, 1975) and Nukumanu (Feinberg, 1995; Haddon & Hornell, 1975; Neyret, 1977; Sarfert & Damm, 1929), and in the model voyaging canoes that Takuu craftsmen still produce for sale to art collectors and tourists. These vessels were 40–50 ft long, constructed with deep-V hulls, rigged with triangular pandanus-leaf sails, and were symmetrical from end to end, making bow and stern identical. The outrigger float was significantly shorter than the hull, and small shelters might be built on the outrigger platform, which was always kept to windward when the vessel was underway. These atolls also produced smaller canoes, most of which were round-bottom dugouts, that might be sailed, poled, or paddled. Since the late nineteenth century, large voyaging canoes have no longer been built. On some atolls like Sikaiana (Donner, 1995), canoes have been almost totally abandoned except for very small vessels that are intended for fishing on the lagoon, although there is evidence of significant canoe voyaging in times past. (According to elderly Duff Islanders, the Sikaiana were in regular communication with Taumako prior to the 1917 influenza pandemic, and they ordered and used large voyaging canoes from Taumako.) Small fishing canoes intended for calm water are also used on Ontong Java, Nukumanu, and

Takuu. Somewhat larger canoes may be used to transport cargo to and from visiting ships or for hauling copra and taro from the outer islets. Nukumanu still construct and use large canoes for voyaging to Ontong Java, across 30 miles of open ocean. Contemporary Nukumanu voyaging canoes may be as long as their predecessors, but they are less carefully constructed and resemble the smaller ones in design. They may be rigged for sail, but Nukumanu prefer outboard motors for propulsion, especially on longer journeys. In 2000, Nukumanu islanders told Feinberg that fiberglass motor-driven boats on all of these atolls are gradually replacing canoes (Figs. 2 and 3).

On Taumako (Duff Islands) and the Polynesian Outer Reef Islands of Nifiloli and Pileni, voyaging canoes are called “canoes of Lata.” Lata, a widely recognized Polynesian culture hero, is said to be the first person to build and sail a voyaging canoe of the type known as *te puke*. These are built with a roundish hull that is hollowed out from a single log. The top is boarded over and made watertight, except for the area enclosed by a riser box, which provides access for bailing and stowage of nonwater-sensitive cargo and ballast. When under sail the hulls are almost entirely submerged. The crew stays on one of two platforms that straddle the riser box and outrigger beams. Although there is one outrigger float (*ama*) per canoe, it may be fashioned from as many as four float timbers lashed together, depending on how much flotation is needed. The crew situates itself on whichever platform is most appropriate for sea conditions and the trim of the cargo. The predominantly submarine hull is subject to less surface tension and wave action than more conventional hulls, making them considerably faster. To the best of our knowledge, this hull design is unique to Taumako vessels. (We must note, however, that few ancient hulls have been recovered from Pacific waters. Perhaps, with further research, we will find evidence of submarine hull shapes from other parts of Polynesia.) Like the vessels of the central outlier atolls, as well as some from the Polynesian heartland (e.g., the Tongan *kalia*), *te puke* are equipped with shelters on the outrigger platform.

islet

Taumako sails are made from panels of plaited pandanus mats, sewn together vertically to form a graceful, slender foil, or delta wing shape. Unlike many Pacific Islanders who have abandoned pandanus sails in favor of cloth, Taumako sailors prefer pandanus, which they say lasts longer and is easy to maintain and repair. The design resembles “crab-claw” sails of Tahiti and Hawai’i as depicted by artists on early European voyages of exploration, but its symmetrical shape, with long, slender, arcing wingtips, has few parallels in Oceania (Fig. 4).

Most canoes of this description have been constructed on Taumako on order from other

communities in the Santa Cruz Islands and elsewhere in the Solomons. In the 1920s, over 200 *te puke* were observed to be sailing in what is now Temotu Province (Davenport, 1968). Generally, the Outer Reef Islanders specialized in navigation while the Taumako specialized in canoe building.

For a period of a few decades in the middle to late twentieth century, construction of *te puke* was almost abandoned because of depopulation and suppression of voyaging by colonial authorities. The last working *te puke* broke up off Nifiloli in 1963, although a few local vessels of other designs kept sailing between Santa Cruz (Ndeni) and the Reef Islands until the early

Seafaring in the Polynesian Outliers,

Fig. 4 *Te puke* type voyaging canoe from Taumako island under sail on open sea

1970s. However, since around 1980 – and particularly since the mid 1990s – interest in actively making and using traditional voyaging canoes has revived, in large part thanks to the activities of the Vaka Taumako Project (see below).

Te puke canoes (*nga puke*, pl.) are distinguished from other Taumako vessels by their very large cargo carrying capacity. They are made of heavier and harder woods than other canoe types, have a riser box that lifts the outrigger beams some 3 ft or so above the top of the hull, have a shelter on the windward platform, and are at least 36 ft in length. Older Taumako state that until Lata made the first *te puke*, they depended on double-hulled *vakalua* for interisland travel. *Nga puke*, being lighter and faster, offered superior performance. One that a group of Duff Islanders sailed from Taumako to Vella Lavella in 1980 was observed by a Solomon Islands government ship to be cruising at a speed of ten knots. (In 1979 people of Taumako built a *te puke* to represent the Solomon Islands at the 1980 Pacific Arts Festival in Port Moresby. The voyage from Taumako to New Guinea had to be cut short for political reasons. Local officials required them to travel via Honiara, the national capital, which meant taking a risky and nontraditional route. Those officials then held the canoe so long that the seasonal winds ceased before the crew could navigate the vessel from Vella Lavella in the Western Solomons to Papua

New Guinea.) With their massive outrig and ingenious lashings, *te puke* are also very strong and seaworthy (Fig. 5).

Te alolili canoes are lighter and faster, designed to carry people and light cargo. They range in length from 18 to 33 ft. The Taumako also make smaller, less elaborate outrigger canoes called *te alotovi*, which may or may not be rigged for sail. And they construct monohulled, nonoutrigger paddling canoes, on which they may either rig lateen sails made of rice bags or add a wooden plank to serve as a motor mount. They use these primarily to transport cargo within the Duff Islands and to visiting government ships. For some purposes they, like other islanders, would like to have fiberglass canoes propelled by outboard motors, and in 2001 there were at least two working outboard engines on Taumako. Scarcity of fuel, however, normally precludes their use. As of January 2002, Taumako still had no fiberglass vessels. However, such canoes from Lata, the Temotu provincial capital, occasionally go to the Duffs on emergency missions.

Canoes on Tikopia and Anuta more closely resemble those documented in the so-called Polynesian Triangle. Anuta is a tiny volcanic island with a small reef flat and no protected water. As a result, Anutan canoes tend to be larger than their Tikopian counterparts. Otherwise, they are similar in design. Hulls are of deep-V construction. They are hewn from a single tree and generally

Seafaring in the Polynesian Outliers,

Seafaring in the Polynesian Outliers,

Fig. 6 Outrigger canoe of *vaka pai manu* type, rigged with rectangular sail, on beach at Anuta island

built up with one plank to increase freeboard. Unlike canoes of the Santa Cruz Islands and the Polynesian atolls to the north and west, Anutan craft have a distinct bow and stern, and the outrigger is always kept to port regardless of one's heading in relation to the wind. They range up to about 35 ft in length and average 20–25 ft, with a few that are much smaller. Virtually all Anutan canoes have the same design, with high gunwales and carefully carved bow and stern covers to minimize shipping of water as one passes through the surf and sails on choppy seas. Anutans and Tikopians who live in the central Solomons, either in Honiara or the Russell Islands, have more sheltered water and less time for fishing than their compatriots at home. Their canoes, therefore, are smaller, are usually designed to be

paddled rather than sailed, are not augmented by gunwale planks, and typically lack bow and stern covers. Canoes of this type are known as *tovi*; the larger, more elaborate canoes with ornately carved bow and stern pieces are termed *vaka pai manu* “birdlike canoes.” The bow and stern pieces (*puke*) are intended to resemble birds (Figs. 6 and 7).

Like the Taumako, Anutans still make their canoe hulls exclusively from local materials – primarily wood and sennit cord. They do not use nails, screws, or other commercial fasteners. They occasionally employ a piece of Styrofoam for caulking, and commercial glue sometimes replaces breadfruit sap to help caulk the joint between the plank and the main hull. However, the only commercial product that they use with

Seafaring in the Polynesian Outliers,

Fig. 7 Anutan outrigger canoe of *tovi* type, on beach in Russell Islands. The canoe is rigged with a lantern holder for catching flying fish at night

Seafaring in the Polynesian Outliers,

Fig. 8 Anutan child paddling a large bowl (*kumete*) through the surf on the reef flat at high tide

any regularity is water-resistant paint, which they apply in an effort to protect the hulls of their larger vessels.

The sail and rigging show more Western influence than the hull. Stays may be commercial rope, and rectangular sails usually fashioned from cotton cloth have replaced the old triangular pandanus-leaf sails. Like many other Pacific Islanders, Anutans were happy to abandon pandanus sails, which become heavy and difficult to handle when they get wet. The rectangular sails were introduced in order to provide more surface area in proportion to the

mast height. This increases the canoe's speed without decreasing stability; the tradeoff is that rectangular sails do poorly beating against a headwind.

In addition to *vaka pai manu* and *tovi*, Anutans recognize outriggerless canoes, which they call *puai vaka* "egg canoes." However, they do not make such vessels. Their closest analogues are large wooden bowls (*kumete*) of the type that might be used for preparing puddings or making turmeric dye. These bowls are vaguely canoe-shaped and can be paddled if the sea is not too rough (Fig. 8).

Sailing Techniques

As Lewis (1972) noted, most of the Polynesian outliers use the Micronesian strategy of sailing with the outrigger to windward. In order to accomplish that, they tack by moving the mast, sail, and rigging to the opposite end of the canoe, converting the old bow into the new stern and vice versa. Tikopians and Anutans have adopted the more common Polynesian strategy of having a distinct bow and stern with the outrigger fixed to the port side of the hull. As a consequence, the outrigger is sometimes in the canoe's lee, and many hulls are constructed with a slight bulge on the port side to help keep the outrigger float from being submerged when the wind blows hard from starboard.

Among outrigger canoes, those of Nukumanu and Ontong Java, with their triangular sails, do a relatively good job of beating into a headwind, and Taumako's *te puke* may do better still. George found that one such vessel, *Vaka Taumako*, could point higher and go faster than her 32.5 ft-long gaff cutter rig. It made better than 5 knots at 75° off the wind in a steep, choppy sea and a 20-knots breeze. In addition to being extraordinarily efficient, the Taumako sail and rigging may be trimmed to suit a wide variety of conditions.

Anutan vessels, with their rectangular sails, do not sail well unless the wind is either astern or abeam. Therefore, Anutans try to arrange their trips in such a way as to avoid having to beat against the wind. For example, their voyages to Patutaka, 30 miles to the southeast, are usually made during the trade-wind season but at a time when the wind shifts temporarily to the north or west. They assume that it will shift back to the southeast within a few days, and they will be able to journey in both directions with a favorable wind. Should they need to travel at much less than a 90° angle to the wind, they either wait for a change in weather, return to their point of embarkation, or stow their sails and paddle into the wind.

Navigation

Those communities that continue moderate- to long distance voyaging have retained much of

their ancestors' knowledge of constellations, movement of astronomical bodies, and star paths. Feinberg (1988, 1995), for example, has documented the continuing astronomical knowledge of Anutan and Nukumanu wayfinders. Conversations with islanders from both communities over a period of several months in 2000 made clear to him that young people have perpetuated this knowledge. At the same time, however, astronomical knowledge in the late twentieth and early twenty-first centuries has apparently declined from what it was a century earlier. Present-day Anutans insist that members of previous generations knew more than they know, and similar views among Nukumanu appear to be confirmed by the reports of Sarfert and Damm, which list many more constellations than islanders recognized in the 1980s.

Both Nukumanu and Anutan navigators maintain their course by swells as much as by the stars, which cease to be helpful during the day or any time the sky is overcast. In this respect, they resemble most other Pacific Island voyagers, many of whom depend on swell patterns even when piloting large ships. Both Nukumanu and Anutans also distinguish between swells and reflected waves, which may be felt at distances of up to 20 miles from land and are useful for making landfall. These are more difficult to discern than ocean swells, and only a few of the most proficient navigators are able to use them effectively. Islanders insist that skill at detecting "land waves" was more widely distributed in their communities in earlier generations. Along with swells, islanders pay attention to wind patterns, which tend to be relatively stable even when stars and the sun cannot be seen.

Like Nukumanu and Anutans, Taumako and Outer Reef Islanders agree that much knowledge of celestial navigation has been lost over the past century. The most authoritative commentator on this point is Taumako Paramount Chief Koloso Kaveia. Kaveia began his voyaging career as a small boy sailing on canoes based at Pileni in the Outer Reefs prior to 1920. Fellow islanders consider him to be the most experienced and distinguished living navigator and voyager. While Kaveia and other Duff Island navigators are

familiar with star paths, however, they consider celestial movements and swell patterns to be secondary to knowledge of the “wind compass” (*nohoanga te matangi*).

Nohoanga te matangi is a comprehensive system that correlates information about wind directions, calendric seasons, and movements of celestial bodies with sea routes. It is not just a wind compass in the unexplained and often partial forms that have been previously reported (e.g., Lewis, 1972). It is a tool, rather like a clearing house or slide rule, for bringing into relationship the various fields of information relevant to planning a particular voyage. Its use also presumes facility with weather magic to control wind and sea states, and this requires good command of the protocols for dealing with one’s ancestral spirits. *Nohoanga te matangi*’s major elements include ten main celestial bodies that are used in navigation plus the two “wing stars” located to either side of each primary star. The “wing stars” are used in cases when the current, sea state, or wind conditions preclude reliance on the central star paths. Navigation also presupposes a working knowledge of *te lapa* – the luminous lightning-like appearances that signal the direction and distance of land (see below).

In addition to wind, waves, and stars, islanders rely on a variety of subsidiary techniques to hold a steady course or to home in on a target island. In recent generations, some of these techniques have been abandoned and receded into legend. For example, Anutans say that dolphins, to which they refer as *nga ariki o te moana* (kings of the ocean) might lead a lost voyager to land. Nukumanu speak in similar terms of meteors, which they term *tanaloa* – the name for one of the great pre-Christian gods in much of Polynesia. Other subsidiary techniques are still relied upon and are apparently effective. Most islanders continue to observe the flight patterns of birds as a technique for land finding. Lewis (1972) has reported patterns of phosphorescence (*te lapa*) which Reef and Duff Islanders continue to employ for the same purpose. George has learned that Taumako navigators can make effective use of this phenomenon at impressive distances. In 1980, Kaveia used *te lapa* to find his way between

the large islands of the Solomons chain, sometimes at a distance of over 110 nautical miles. It also appears that the appearance of *te lapa* from each island or reef has a distinctive character. The phosphorescent flashes shoot across the ocean surface and are easiest to see in the interstices of intersecting waves.

Social Relations

On Nukumanu and Anuta, navigators are admired and respected for their skill, but they do not hold a formal position. An Anutan navigator is known as *tau tai mau kaavenga* (expert at finding star paths), which is more a description the navigator’s skill than a title. In neither community are there rites of passage that mark one’s transition to navigator status; most men have some knowledge in this area, but some have considerably more than others. An expert navigator may come from any descent group and any social stratum, from chiefs to commoners. On both Nukumanu and Anuta, education in the skills of boat building, sailing, and navigation also is informal. There are no navigational schools, nor is there any formal apprenticeship. A novice watches the experts and learns primarily through emulation.

On Taumako, the navigator is a highly trained specialist. Kaveia apprenticed for many years with Pileni relatives, then married and returned to Taumako where he studied navigation with his father. In addition, a Taumako navigator must have a canoe and, in earlier times, contacts or partners on distant islands as well as access to red feather money and other valuables. An enterprising person of low rank can acquire the necessary assets, but high-status males have a clear advantage. Today, education in canoe building and navigation has been incorporated into the Vaka Taumako Project in an attempt to ensure the maintenance of older knowledge and practices.

Change

Seafaring practices have changed in all the Polynesian outliers over the past two centuries, but to

different degrees and in different ways on different islands. The great voyaging canoes (*vaka hai laa* or *vaka fai laa*) of the central outlier atolls have not been produced since the late nineteenth century, but sailors from Nukumanu and Ontong Java continue to make the 30-mile voyage between the two atolls, and they sometimes still use wooden outrigger canoes powered by sail. Sikaiana, at the opposite extreme, has entirely given up production of ocean-going canoes. Even Anutans, whose seafaring activities depend entirely on outrigger canoes of traditional design, who regularly voyage 60 miles to Patutaka and back, and occasionally still sail to Tikopia, a 150-mile round trip, have replaced pandanus sails with cotton cloth or (occasionally) plastic sheets.

While much has been lost, some of the outliers have nonetheless maintained a good deal of their seafaring knowledge and continue to put it to good use. Anutan reliance on wooden *vaka pai manu*, held together with sennit cord, has continued uninterrupted to the present day. Equally impressive is Taumako's self-conscious effort to reverse a decline in seafaring knowledge through the Vaka Taumako Project – an educational enterprise intended to promote mastery of traditional canoe-building and voyaging skills among younger community members by constructing several *te puke* and *te alo* voyaging canoes and sailing them to remote destinations under the direction of skilled navigators. In 2001 the Vaka Taumako Project launched the first class of over 50 students. The students aim to learn eight necessary skills for building and navigating voyaging canoes using only traditional Polynesian methods. A 65-foot by 40-foot canoe house was erected to shelter and maintain three vessels that have been produced by the project. It is hoped that this canoe house will also serve as a classroom and archive for Taumako voyaging knowledge, and to accommodate visiting students and voyagers.

Seaports of the Maya

Rafael Cobos

The marine seacoast of the Maya area extends for more than 1,000 miles and is composed of different environments, which include sandy and rocky beaches, mangrove swamps, and riverine deltas (Fig. 1). These environments were occupied during pre-Hispanic times by individuals who founded numerous communities and built an elaborate infrastructure that caused the rise of seaports during the Preclassic (1200 BCE–AD 200), Classic (AD 200–1050/1100), and Postclassic (AD 1050/1000–1550) periods (Andrews, 1990; Nondédéo, 1998; Vail, 1988).

Ancient Maya seaports are found either directly on the coast or less than 2–3 miles inland. As with other seaports in the world, ancient Maya seaports were permanently settled by individuals engaged in different duties that included the maintenance of their community by political, economic, social, and ideological activities. Ancient Maya seaports also provided shelter to sailors, traders, and the merchandise they transported. They facilitated the transportation of goods and gifts that were moved between close and distant regions; they were also used to satisfy basic as well as secondary needs of communities located a few miles inland or hundreds of miles away.

Early explanations about the function of ancient Maya seaports were put forward during the first half of the twentieth century. For instance, it has been suggested that settlements such as Jaina, located in western Yucatán, and Xcaret, located in front of Cozumel Island, functioned as an island necropolis and a port of embarkation to an offshore island respectively. Over the past 50 years, however, the Maya marine seacoast has been the focus of several systematic archaeological investigations, and previously assigned functions of pre-Hispanic coastal communities such as Jaina have been rejected. Regarding Xcaret, archaeological

investigations have corroborated its role as a port of embarkation to Cozumel Island as well as a complex seaport that functioned during the Classic and Postclassic periods (Andrews, 1990).

Systematic research conducted on several pre-Hispanic Maya coastal communities that functioned as seaports indicates that these ancient settlements were arranged in distinctive ways and date to different periods. The unique characteristics of ancient Maya seaports were the result of social, economic, political, and ideological processes that each of them experienced throughout time. For instance, archaeological investigations have revealed three different forms through which these marine seacoast settlements interacted with other marine coastal sites as well as with inland settlements. These three forms of interaction include the coastal port associated with a regional capital, trans-shipment seaports, and the seaport as a social, political, and economically independent unit. A description of each one of these follows.

The Coastal Port Associated with a Regional Capital

Isla Cerritos and Chichén Itzá exemplify the interaction and dependency generated between a top-ranking political unit and a lesser-ranking site. Isla Cerritos is an island off the northern coast of Yucatán whereas Chichén Itzá is located 55 miles directly south and inland (Andrews, Gallareta, Robles, Cobos, & Cervera, 1988; see also <http://www.ncf.edu/andrews/Index.html>). The material expression of that dependency suggests that the coastal community of Isla Cerritos was subordinate to the political and economic control of Chichén Itzá to the extent that the main architectural group of the island reproduces on a lesser scale a group of buildings that characterize the regional capital, which include a temple, altar, and colonnaded hall. The contemporaneous nature of the coastal port and the regional capital is demonstrated by the presence of the same types of commercial and utilitarian ceramics. Obsidian found in the coastal port as

Seaports of the Maya, Fig. 1 Maya seaports located in México and Belize

well as in the regional capital reflects the same supply sources. The remains of shells discovered both in Isla Cerritos and in Chichén Itzá are integrated into the body of archaeological evidence, which demonstrates the interest that the regional capital had in making its presence felt in a very specific sector of the northern Yucatán coast between AD 900 and 1050/1100.

It has been proposed that other settlements located on the seacoast of Belize functioned as ancient Maya seaports of major inland capitals. The examples include Marlowe Cay associated with Altun Ha, Ramonal-Condemed Point linked to Shipstern, and the Northern River Lagoon associated with Colhá. However, the relationship between Marlowe Cay, Ramonal-Condemed

Point, Northern River Lagoon and major inland capitals continues to be speculative, because none of these Maya seaports has been investigated in detail.

Trans-shipment Seaports

This type of seaport, which served a specialized function, is recognizable by the following characteristics: they are small settlements in comparison to other inland communities, they exhibit a minimum of formal architecture, they are strategic points in the movement of commodities and/or merchandise among regions, and they contain a wide variety of exotic goods by having been part of a complex system of trade or exchange (Inurreta, 2004). To date, the best examples of trans-shipment ports analyzed in the Maya area are San Juan, Chac Balam, Moho Cay, Wilde Cane Cay on the coast of Belize, and Uaymil on the northern coast of Campeche (Guderjan & Garber, 1995; Inurreta, 2004; McKillop, 1996, 2005).

For instance, Uaymil emerged as an important coastal port on the northern Campeche coast after AD 800. Uaymil maintained a close relationship with Uxmal and Chichén Itzá, and the archaeological evidence uncovered at Uaymil confirms that this port was founded during the apogee of those two major political units. Uaymil functioned as another link in the chain of coastal sites that facilitated the transport of commodities between Chichén Itzá, located in central Yucatán, and the regions of the western Guatemala highlands, central Veracruz, central México highlands, and western México. When we consider the very strategic location of Uaymil on the northern Campeche coast, along with its internal characteristics and the archaeological materials found at the site, we can interpret that Uaymil functioned as a trans-shipment station. Uaymil's role was to facilitate the movement of merchandise and goods that eventually arrived at Chichén Itzá via Isla Cerritos. Evidently, Uxmal - the great capital of the western portion of the northern

Maya lowlands located 55 miles inland – also benefited from the specific role that Uaymil played during the tenth and eleventh centuries (Inurreta, 2004; <http://www.famsi.org/researchreports/bysite/uaymil>).

The Independent or Autonomous Seaport

The third type of seaport documented in the Maya area is characterized by its autonomous role. In other words, this type of port was a social, political, and economically independent entity. The autonomous seaport was never under the jurisdiction or hegemony of larger and powerful political units, and this condition allowed such a port to rise and flourish in several environments and during different periods in the Maya area. For instance, Cerros in Belize was an independent seaport located in a region where the riverine delta meets the open sea. By the Late Preclassic period, Cerros functioned as a complex seaport with a site center housing monumental buildings with elaborate architecture and a large residential zone surrounding the site center. The strategic position of Cerros on the coast of northern Belize allowed this site to have access to commodities and merchandise that were transported from inland to the Caribbean Sea or vice versa (Robertson & Freidel, 1986).

Xelhá was another autonomous seaport located on the east coast of the Yucatán Peninsula. Xelhá was first settled during the Late Preclassic period or around 100 BC, and was continuously occupied until the sixteenth century (Andrews, 1990). The archaeological evidence suggests that Xelhá functioned as an independent seaport during the Early and Late Classic periods and seems to have played a key role in the exchange system of obsidian, jade, and other goods that circulated along the Caribbean Sea and between Central America, Belize, and northern Yucatán (Guderjan & Garber, 1995; McKillop, 1996; McKillop & Healy, 1989). The role played by Xelhá as an important seaport

might be attributable to its geographic position along an important marine route that was established by the fifth century.

At Cozumel Island the site of San Gervasio became a seaport by the ninth century. San Gervasio is located in the northern sector of Cozumel and the archaeological evidence suggests two important moments of occupation at the site. The first of these moments dates between the eighth and tenth centuries and corresponds to the Classic period. The second moment of occupation dates from the eleventh to the sixteenth centuries and this period ends around 1518 when the first European conquerors arrived at Cozumel. The role played by San Gervasio as an autonomous seaport during the pre-Hispanic era is attributed to two precious goods produced at the island – cotton for textiles and honey (Sabloff & Rathje, 1975). Sixteenth-century historical documents confirm the production of cotton and honey at Cozumel whereas the archaeological data corroborate the important role that these precious goods must have had on the economy of San Gervasio (Roys, 1957).

Other Maya seaports that rose as independent political entities include Jaina, Xcambó, and Tulum. The first two seaports flourished during the Classic period whereas Tulum's apogee dates to the Postclassic period (Andrews, 1990). The importance of Xcambó as a seaport is attributable to its control of the large salt beds located on the central coast of Yucatán. It seems Xcambó controlled the production of salt and exported this mineral to other communities located in the Maya area and beyond. The function of Jaina and Tulum as seaports might be explained by their strategic midpoint position along the commercial sea routes that dominated the Gulf of México (Jaina) and the Caribbean Sea (Tulum). In fact, Tulum was spotted by Spanish conquerors early in the sixteenth century and they described it as a town larger than Seville.

This information represents a small part of the tremendous potential that awaits discovery

regarding the function of ancient Maya seaports. Future archaeological investigations will continue to contribute to the increase in our knowledge of the features that characterize such complex coastal communities.

Seki Kowa

Shigeru Jochi

Osaka Kyoiku University (Osaka University of Education), Osaka, Japan

SEKI Kowa, also called Takakazu, was born about 1642, probably in Fujioka, Gumma, Japan. Seki is his surname, and Kowa is the Chinese reading of characters, so the Japanese reading is Takakazu. His middle name is Shinsuke and pen name is Jiyutei. He was born into a samurai warrior family, the second son of UCHIYAMA Shichibei Nagaakira (unknown–1662) (In official documents, Uchiyama Nagaakira died in 1646, but Seki Kowa's youngest brother, Uchiyama Nagaaki (1661–1725) was born in 1661. So Uchiyama Nagaakira was alive in 1661 at least. More, Uchiyama Nagaakira's father was died in 1662 in these documents, thus we conclude that Uchiyama Nagaakira was died in 1662 (Jochi 2005, p. 19).), and he became a son-in-law of SEKI Gorozaemon (Gorozaemon is a middle name, and the first name is unknown. Perhaps he is Seki Yoshinao (1591–1673) or part of another Seki family, Seki Toyofusa (about 1632)) and succeeded to the SEKI family. First he became an auditor of TOKUGAWA Tsunashige (1644–1678) at Kofu (now Kofu, Yamanashi) about 1661, then a chief of the meal service section (His annual salary was 200 *pyo* (150 kg of rice)). He lived at Yamabushi-cho (now Minami Yambushi-cho, Shinjuku, Tokyo) about 1695. In 1704, he became a chief of the Store Room of the Shogun's family, and finally became a landlord of a 300-person village. (His annual salary was 300 *pyo*, which is the same as being a landlord of a 300-person village. The samurai warrior who earned over 200 *pyo* could be received in an audience by the Shogun) The Shogun's government normally kept the family records of landlords. But since Seki Kowa's son-in-law,

Shinshichiro (1690–unknown) lost his position, owing to his gambling activities, we cannot fix even Seki Kowa's birth year exactly.

Seki studied mathematics under TAKAHARA Yoshitane. Takahara Yoshitane was a disciple of MORI Shigeyoshi, who wrote the *Warizansho* (Books of Division 1622), the second mathematical book in Japanese. But Takahara Yoshitane was little known for his mathematical works. Basically Seki taught himself mathematics, using famous texts of Chinese and Japanese mathematicians, such as the ► *Yang Hui Suan Fa* (Yang Hui's Method of Computation 1275), which he copied in 1661, and SAWAGUCHI Kazuyuki's *Sampo Ketsugi Sho* (Solving Mathematical Questions 1659). He amended works of other mathematicians, and founded the Seki-ryu school. He is generally considered the founder of Japanese mathematics (Figs. 1, 2, and 3).

The *Tianyuanshu* (lit. Celestial Element Method, Chinese Algebra System) had already been introduced from China by Zhu Shijie's *Suan Xue Qi Meng* (Introduction to Mathematics Studies 1299). This system was for the *Suan Chou* (*Sangi* in Japanese) – counting rods, in the Song and Yuan dynasties in China. In the Ming dynasty, however, new counting tools, *Suanpan* (*Soroban* in Japanese) – abacus – became popular, since no mathematicians understood the *Tianyuanshu* even in China. Japanese mathematicians taught the *Tianyuanshu* by themselves using a Korean edition of the *Suan Xue Qi Meng*. Sawaguchi Kazuyuki was the first Japanese mathematician who mastered it.

Traditional Chinese mathematics used counting tools, *Suan Chou* or *Suanpan*; they had no algebraic symbols. The position of rods (or beads of *Suanpan*) indicates numbers and the power of unknown numbers. This system could only operate with unknown numbers. Seki Kowa created *Tenzan-jutsu* (Japanese algebra system), which could operate with unknown formulae, making it possible to solve complicated problems.

Seki called his method *Endan-jutsu* or *Bosho-ho* (Methods of writing by the side).

Seki Kowa, Fig. 1 Picture from the Kojukai, Shimminato, Toyama

Seki Kowa, Fig. 2 Stamp issued in 1992

MATSUNAGA Yoshisuke (1693–1744), a mathematician of the Seki-ryu school, renamed it *Tenzan-jutsu*. Seki indicated one unknown number using one Chinese character and created the symbols of calculations and powers. And he solved the $1,458^\circ$ equation in the *Hatsubi Sampo* in 1674.

His works cover the following categories:

1. Japanese algebra system
2. Solution of higher degree equations
3. Properties (e.g., number of solutions) of higher degree equations
4. Infinite series
5. Approximate values of fractions
6. Indeterminate equations
7. The method of interpolation
8. Obtaining Bernoulli numbers using *Ruisai Shosa-ho*
9. Computing the area of polygons
10. Principle of the circle
11. Newton's formula using the *Kyusho* method
12. Computing the area of rings
13. Conic curve lines
14. Magic squares and magic circles
15. Mamakodate (Josephus question) and Metsuke-ji (the game of finding a Chinese character)

These categories had been very problematic before him, and he offered excellent solutions.

In 1712, TAKEBE Katahiro (1664–1739), Seki's student, edited Seki's works and published the *Katsuyo Sampo* 1 year before Bernoulli's *Ars Conjectandi* (1713). Seki obtained Bernoulli numbers using the *Ruisai Shosa-ho* system. It is a typical example of his mathematics. He also worked with what we call Pascal's triangle.

Seki computed to higher powers and obtained the fraction numbers of the last line of Table 1;

$$\begin{aligned} \lambda_0 &= 1, \lambda_2 = 1/2, \lambda_3 = 1/6, \lambda_4 = 0, \lambda_5 = -1/30, \\ \lambda_5 &= 0, \lambda_6 = 1/42, \lambda_7 = 0, \lambda_8 = -1/30, \lambda_9 = 0, \\ \lambda_{10} &= 5/66, \lambda_{11} = 0 \end{aligned}$$

Seki Kowa, Fig. 3 Seki's tomb at Jorin-ji temple, Ushigome, Edo (now Benteen-cho, Shinjuku, Tokyo)

Seki Kowa, Table 1 Shosa-ho's table, Chap. 1 of the Katsuyo Sampo (1712)

	1	1											
x^2	1	2	(1)										
x^3	1	3	3	(1)									
x^4	1	4	6	4	(1)								
x^5	1	5	10	10	5	(1)							
x^6	1	6	15	20	15	6	(1)						
x^7	1	7	21	35	35	21	7	(1)					
x^8	1	8	28	56	70	56	28	8	(1)				
x^9	1	9	36	84	126	126	84	36	9	(1)			
x^{10}	1	10	45	120	210	252	210	120	45	10	(1)		
x^{11}	1	11	55	165	330	462	462	330	165	55	11	(1)	
x^{12}	1	12	66	220	495	792	924	792	495	220	66	12	(1)
Power	1	2	3	4	5	6	7	8	9	10	11	12	13
	1	$\frac{1}{2}$	$\frac{1}{6}$	0	$-\frac{1}{30}$	0	$-\frac{1}{42}$	0	$-\frac{1}{30}$	0	$\frac{5}{66}$	0	

These are just the same as Bernoulli's numbers. He was able to compute too much higher numbers than other mathematicians before him, and he obtained the general rule by the inductive method. He, and mathematicians of his school, used this system habitually.

Seki died in Edo (now Tokyo), on December 5, 1708 (October 24, 1708, in the Japanese calendar).

Settlements in Egypt: Alluvial Settlements in the Nile Valley (and Delta)

David Jeffreys

The River Nile forms a long thin strip of alluvial valley floor, rarely more than 15 km wide, through the hyper-arid desert of north-eastern

Africa before fanning out into the Nile Delta north of Cairo. The Nile is fed by two main tributaries, the Blue and White Niles, which merge near Khartum in Sudan, and a minor tributary, the Atbara. The Nile Delta is now reduced to two main distributary channels, the Rosetta (Rashid) and Damietta (Dumyat) branches, with outlying residual canals serving Alexandria in the west and Pelusium in the east; in antiquity up to seven channels are recorded.

Before the construction of the first Aswan Dam in the late nineteenth century, the Egyptian Nile valley and the delta were subject to annual flooding due to monsoonal rains over the Ethiopian plateau which boosted the volume of the Blue Nile. The flood lasted several months, rising in late spring and receding in early autumn, and brought a new deposit of high-nutrient alluvium which provided the basis for Egypt's successful agricultural economy. Despite the popular picture of an idyllic, non-labour-intensive labour cycle, this flood-recession economy was vulnerable, being almost entirely dependent on a successful or "perfect" flood (i.e. neither too high nor too low), and left little resilience to fluctuation (Hassan, 1993, 1997): there is for example hardly any evidence for man-made water storage facilities or canals serving marginal or extended catchment areas.

During the Epipalaeolithic period the Nile was building in response to changes in sea level; subsequently there was a down-cutting phase, with the result that the only surviving Palaeolithic sites are now preserved in the high terraces flanking the existing river valley. During the Neolithic (from 10,000 BCE) the valley had again been building with alluvial sands and silts accumulating at the rate of about 10 cm per century. The valley floor today presents as a virtually dead flat plain dropping slightly to the eastern and western edges, and forming a slightly convex appearance with the highest, heaviest and newest sediments closest to the river. Throughout Egypt and Sudan the course of the Nile and its subsidiaries is of relatively low sinuosity, although this changes across the delta flood plain.

Upstream of Aswan and the first cataract lies that section of the valley known as Nubia (also

Kush, Wawat or Napata); during the 3,000 years of pharaonic culture in Egypt there was a long and complex history of exchange and interaction between the two polities. Culturally Egypt and Nubia seem to follow a similar trajectory up to the foundation of a unified cultural and political Egyptian state in about 3,000 BCE, with similar traditions in their lithic and ceramic industries. Thereafter Egyptian material culture develops differently into the highly distinctive pharaonic style in dress and body decoration, pottery production and metalworking, visual representation, and architecture. In Egypt both valley and delta were divided administratively into large land parcels or provinces called *nomes*, each with a local capital. In the Valley these nomes generally straddled the river; in the Delta they were determined by the changes in the distributary system and usually lay between the main channels. In Egyptian texts Nubia is recorded in less detail, and seems to be divided into ethnic/geographical zones: the part north of the second cataract, closest to Egypt's southern frontier at the first cataract, was under Egyptian control through most of the second and first millennia BCE. The desert regions outside the alluvial corridor were only lightly inhabited, except for the Saharan oases, but were exploited for their mineral contents, especially gold, high-grade building and sculptural stones, and pigments, and as an access to the trading routes of the Mediterranean and Red Seas and the African interior.

Settlement archaeology in Egypt is, astonishingly, still in its infancy (O'Connor, 1993), and may never achieve its full potential with the onset of modern threats including industrial and residential development, climate change and the rise in the groundwater table brought about by the construction of the Aswan high dam in the 1960s. Traditionally the emphasis in exploratory fieldwork has been on the burial grounds of the valley edges and visible monumental architecture within established archaeological sites such as Thebes (Luxor). A critical factor in the recognition and recovery of information from Nile valley settlements is the mean rise of the valley floor over the past 5,000 years, which has had the effect of obscuring even quite well established

settlements or those which have been abandoned by the river as it has shifted course. Stratigraphically shallower and more deeply buried sites, such as the older, shorter-lived towns, and ephemeral rural habitations of all periods, tend therefore not to survive unless they are on the higher ground at the valley edges. We are just beginning to understand just how much settlement archaeology has yet to be recorded from the examples of sites such as Avaris-Piramesse, the sixteenth- to twelfth-century royal capital in the northeastern delta also known by the modern names of Tell el-Daba/Qantir (Bietak, 1996), where magnetometer survey has recently revealed huge areas of built environment lying beneath what is now agricultural land which is in private or municipal ownership. In Memphis, a far more extensive settlement area was visible in the eighteenth and nineteenth centuries than can be seen today. How zones such as these are to be treated in the future is yet to be resolved: no effective strategy has yet been proposed for their management, and archaeologists currently proceed largely through private negotiation, returning the land for agricultural or other destructive use after survey and/or excavation.

In Egypt, discussion of settlements has therefore focussed until recently on an impossibly small sample of sites which are almost all atypical of conditions in the Nile valley, leading one leading Egyptologist in the past to suspect that pharaonic Egypt was a "civilization without cities" (Wilson, 1960). The handful of sites most often referred to are:

- The Middle-Kingdom (Twelfth Dynasty, eighteenth century BCE) site of Illahun (also known as Lahun or Kahun);
- The New Kingdom (fifteenth-fourteenth centuries) artisan village of Deir el-Medina on the Theban west bank;
- The newly discovered workers' quarters to the southeast of the Giza pyramids; and
- Particularly the large royal Eighteenth Dynasty (fourteenth century) town of Amarna, including its outlying suburbs, flanking necropolis, and another artisans' compound somewhat similar to Deir el-Medina.

None of these towns are strictly speaking “alluvial”, however: they are all establishments built (probably deliberately) on the desert edge, whose layout was almost certainly unaffected by the river, and apart from Amarna they are attached to specific monumental building projects, all funerary. Paradoxically there is better data for Nubia, largely due to the intensive series of archaeological surveys in that region, especially the international UNESCO project in the 1960s in advance of the construction of the Aswan High Dam (Säve-Söderbergh, 1987). Some of the best-known settlements of all periods are now those in Nubia, as for example the large town and cemetery at the local capital of Kerma, lying in the Nubian heartland above the second cataract (Bonnet, 1995, 2000).

In both Egypt and Nubia the tendency was to construct the main settlements in the two main areas not constricted by the floodwaters, that is on the desert margins and the riverside levees (Butzer, 1976). It is no accident that many of the earliest known settlements are on the lower desert regions to the ► east and west of the main alluvial zone, although this itself raises the question whether traces of settlement in other parts of the valley might have been removed by movements in the main and subsidiary channels. In the Delta settlement was more or less confined to natural marine and riverine sand banks (often called “turtlebacks”) projecting above the general level of the flood plain. Largely due to the lack of any effective national survey strategy over the years, the impression is given of a gradual migration of settlement from the desert to the flood plain, as seen in the case history of the important pre- and proto-dynastic site of Hierakonpolis (Hoffman, Hamroutsh, & Allen, 1986). Regional studies at this site and elsewhere (e.g. Memphis) have shown that river movement in both directions was a determining factor in the success and survival of flood plain communities, and the study of post-pharaonic settlements has shown that viability was dependent on the means to provide high ground beyond the reach of the floodwaters. This might be through lateral migration following the levees, or the rapid vertical development of residential building to maintain

high, dry living conditions. Over time continued occupation must have been impossible to sustain in certain areas: there are some graphic accounts in more recent times of urban blight due to the rising water level, and examples of structures dating from the Late Antique (Byzantine) period having to be abandoned during the seventeenth to nineteenth centuries as the mean level of the inundation gradually rose. Many towns co-operated in the maintenance of river defences on an annual basis, and the fear of their failure is occasionally alluded to in the pharaonic literature. Paradoxically, religious sites in valley regions were especially vulnerable, because they tended to remain low-lying: they were sacrosanct and did not attract vertical accretion through new construction over the decay of earlier building fabric. There is even some evidence that temples were in fact occasionally flooded: such events were regarded as catastrophic, despite the symbolic inundation-based character of religious architectural ideology. It is worth remembering that while this was an ever-present danger in antiquity and into medieval times, conditions have been quite different for the past century, with perennial irrigation, and increasing urban and suburban sprawl, now possible through the construction of the successive Aswan dams. An appreciation of former living conditions is therefore possible today only through pre-twentieth century documents, notably the excellent series of early landscape photographs dating from the mid-1800s to the early 1900s.

Other considerations aside, it is clear that a seasonal pattern in behaviour and mobility must have applied to the annual rhythm of urban living: during the sowing and harvesting seasons, farmers may well have spent most of their time in temporary accommodation in the countryside, migrating to the desert edges and the main urban areas during the flood. In view of the impermanence of many kinds of rural and at least some kinds of urban habitation, it is perhaps interesting that there should be evidence of a considerable attachment to place. Eulogies of cities survive in the written record, probably the best known being a “hymn” to the city of Memphis (Camino, 1954).

The more typical types of flood plain town share several defining characteristics. Some, but by no means all (and perhaps even a minority) had defensive walls, although the river and municipal earthworks seem to have doubled as military defences; all known large conurbations contain at least one religious centre, with the identity of the cult varying with location; these temples and shrines often had enclosure walls of their own, which have a defensive appearance but are not necessarily built primarily for that purpose (Smith, 1998). Future work may confirm the suspicion that some major cities, such as Memphis and Thebes, which are often described as capitals, may at times have been long ribbon developments built along the river banks rather than the more familiar model of a highly nucleated, densely occupied urban core (Jeffreys & Tavares, 1994).

The only complete town site that survives today in any detail above ground is Amarna, built by the pharaoh Amenophis III and his son Akhenaten (Amenophis IV) in the fourteenth century BCE as a breakaway royal city for the celebration of a new solar cult (Kemp & Garfi, 1993). Significantly this is one of only a very few urban regions to be surrounded by boundary markers in the form of rock-cut inscriptions declaring the intention of the ruler, ranged along both sides of the valley but in sight of the town centre. This was probably because the territory for the new foundation was appropriated from the existing nearby provincial capital of Khmunu (Classical Hermopolis Magna, modern Ashmunein), although the major part of the town is on the low desert, not the alluvial plain, probably to maximise the agricultural yield of the requisitioned section of valley floor. Amarna consists of distinct zones representing various discrete functions:

- Residential zones of all social ranks (royal palaces, elite villas interspersed with dependents' quarters, and purpose-built artisanal compounds);
- Religious (temples and solar shrines), economic (food storage and food preparation areas);

- Administrative (police barracks, libraries or storage for diplomatic correspondence) and
- The outlying mortuary districts, including the royal tombs, segregated from the private tombs in a valley due east of the town centre.

Amarna illustrates an interesting tendency in settlement selection, which highlights the importance of landscape symbolism: the "royal valley" is thought to focus sight lines on the central feature of the rising sun, and is embodied in the Egyptian name of the town, Akhetaten ("horizon of the Aten" or sun-disk). In the same way prominent landscape features at other sites acquired symbolic importance, notably at Thebes with its pyramid-shaped mountain on the west bank, and Memphis, at the southern apex of the Delta, with its high-profile layered cliffs to either side (possibly the origin of its earliest name "White Walls").

Even within communities some common features can be identified. Temples conform to a highly distinctive and recognisable pattern, with almost universal features such as the twin-towered pylon featuring flagpoles and monumental statuary, colonnaded courtyards and hypostyle halls with clerestory windows and embrasures; dark and restricted inner sanctuaries; artificially created sacred lakes, and not infrequently causeways, often flanked by ritual statuary such as sphinxes, which linked separate enclosures. There even seems to be a standard plan for houses, the quadripartite ground floor layout incorporating an entrance chamber, communal room and split back section used for different purposes and sometimes featuring a stair to an upper storey or roof terrace (there is evidence for multi-storey structures from both archaeological and representational evidence). Living units of this kind usually occur in terraces along axial or subsidiary streets and alleys, as at Amarna, Deir el-Medina, Karnak and Memphis. Other evidence comes from funerary architecture: it is very likely that tomb plans at different times reflect the general layout of town houses as also illustrated in tomb scenes, with (for example in the New Kingdom) entrance halls, atria that might contain pools or gardens, and back rooms which become

sanctuaries and statue rooms in the funerary context. Some tombs at this time have miniature pyramids over or behind the sanctuary, which are certainly an exclusively funerary feature.

For elite residential structures we are more or less dependent on Amarna, where they take the form of villas or compounds freely dispersed through the northern part of the city, and Illahun, where they form a suite of terraces either side of the main street. Relatively few royal palace structures are recorded in any detail (Malqata at Thebes; Piramesse/Qantir in the delta; three separate palace compounds at Amarna; Balat (Ayn Asil) in the Dakhla Oasis (Soukiassian, Wuttman, & Schaad, 1990); the short-lived early New Kingdom site of Deir el Ballas just north of Thebes; and a supposedly “ritual” palace at Memphis). There are in addition small “palace” structures incorporated in the large mortuary temples of the Theban west bank, especially those of Ramesses II (the Ramesseum) and Ramesses III (Medinet Habu) (O’Connor, 1989).

Sexagesimal System

Marvin A. Powell

The sexagesimal system was an ancient system of counting, calculation, and numerical notation that used powers of 60 much as the decimal system uses powers of 10. Rudiments of the ancient system survive in vestigial form in our division of the hour into 60 min and the minute

into 60 s. Origins of the system of counting are essentially irretrievable because they lie in the period before the invention of writing. They are associated with the ancient Sumerians, whose language incorporated the only known system of sexagesimal counting. The Sumerians were probably also the inventors of the system of calculation, which seems to have its origin in a system of counters (small clay objects also referred to as tokens or calculi) representing the units 1, 10, 60, 60×10 , 60^2 , $60^2 \times 10$, and 60^3 . This counter-calculation system may go back as far as ca. 3500 BCE. The method of numerical notation apparently originated from the system of counters by adapting it to a form that could be represented in writing when the first writing system was invented ca. 3000 BCE.

By 2000 BCE this had developed into a system of sexagesimal place notation that functioned like our decimal system but with several important distinctions. Whereas the decimal system uses ten unique symbols, plus a period or comma to separate fractions from integers, the fully developed sexagesimal system of notation used only two unique symbols (those for one and ten) and essentially ignored our distinction between fractions and integers. These features, as well as lack of a symbol for zero, reflect its origins in the system of calculating with counters: zero would not have been represented in a system of counters (obviously, one does not count something that does not exist), and unique symbols for the integers 1–60 would have been excluded for practical reasons. Lack of a distinction between fractions and integers goes back to the fact that fractions are essentially alien to prehistoric systems of counting. Names for small quantities that we would call fractions are based on subdivisions of the weight system (*mina* and *shekel*) and were clearly not thought of as fractions in our sense of the word. In keeping with this picture is the symbol for medial zero that appears in Babylonian mathematical texts of the late first millennium BCE. This so-called *zero* is really nothing but a “spacer” symbol and reflects the practice (occasionally observable in surviving texts) of leaving a blank space where we would place a zero.

During the third millennium BCE, this Sumerian sexagesimal system was adopted, along with

other features of Sumerian culture, by Semitic-speaking Akkadians, and the Akkadian language, which – like Sumerian – was written in cuneiform script on clay tablets, served as the vehicle for its diffusion and preservation. As an essential part of the education of scribes, it was still very much alive when Greeks conquered the Near East in the time of Alexander the Great. The two centuries of Greek presence in Mesopotamia (330–129 BCE) facilitated the incorporation of Babylonian mathematical astronomy into the Western tradition, and with it also came knowledge of the Babylonian sexagesimal system. This, however, seems never to have been used systematically by Greeks outside of Babylonia. Division of the circle into 360° is a vestige of the Babylonian system that has been transmitted to us by the Greeks.

Modern knowledge of the existence of an ancient sexagesimal system goes back as far as the recovery of Greek mathematics, beginning in the Renaissance. Little, however, was known about its true character until the middle of the nineteenth century when decipherment of cuneiform writing revealed the system in its developed form of the first millennium BCE. Speculations about its origins have tended to postulate conscious creation, as opposed to gradual evolution. The 360-day year and choice of 60 as base (because 1, 2, 3, and 5 are all prime factors) are among these theories, all equally without evidence. Only in the twentieth century has the Sumerian system of counting become relatively well understood, and the role of clay counters as prototypes of number symbols has only become clear in the last decade.

Shamanism in Pre-Columbian Mesoamerica

Keith Jordan

Shamanism is a term used by anthropologists and historians of religion to describe similar systems of religious thought and practice centered on the role of ritual specialists who enter trance states in order to communicate with the supernatural world for the benefit of their communities. Derived from an indigenous Siberian term for such a practitioner, shamanism is distributed through Asia from Siberia south to Korea and Vietnam. Across the Pacific, it is characteristic of Inuit culture and of many Native American groups throughout North, Central, and South America. It has been used as a model for understanding religious experience and ritual process in New Guinea and other regions of Oceania and to classify the belief systems of peoples from the San Bushmen of southern Africa to the pre-Christian Lapps. It has been posited as the first human religion, the inspiration behind the cave art of Ice Age Europe, and even suggested as prevalent in Bronze and Iron Age Europe.

The shaman is a specialized ritual practitioner who is adept at entering altered states of consciousness understood as journeys to the spirit world. Ritual, asceticism, music, and hallucinogenic plants may be employed to facilitate entry into visionary experiences. The other world entered by the shaman may be conceptualized as the land of the dead, the realm of animal or nature spirits, or the domains of various deities. At least in Asian and American shamanism, the universe is pictured as divided into upper, middle and lower worlds, connected by a central vertical axis, often a World Tree spanning the cosmos from the bottom of the underworld to the farthest regions of the sky. The shaman is able to visit these other worlds by traversing the central axis or similar portals, often via a state experienced as flight, in order to interact with supernatural beings for the good of the community. The

purpose of the voyage may be to obtain cures and defeat witches on behalf of an individual client, as is frequent in small hunter-gatherer societies, or to control weather, promote the fertility of game and agriculture, and predict the future. Generally, shamans are “called” to their vocation by unusual hallucinatory experiences, personality traits, dreams, or by a prolonged or severe illness. They train by serving as apprentices to older shamans, and frequently attain full status by initiation rites and/or visionary experiences in which they are symbolically killed and reborn to their new identities. In many varieties of shamanism, the specialist cultivates a relationship with an animal spirit as a familiar and/or alter ego, and is believed to take the form of this animal when traveling the spirit world.

Shamanic practices are still prevalent among some contemporary Native Mesoamerican groups, notably many Maya communities in Chiapas, Yucatan and Guatemala, where shamanism mingles with Christian beliefs, and the Huichol of northern Mexico. Because of these ethnographic observations and because of the shamanic features of pre-Columbian cosmologies, anthropologists and art historians have employed shamanism extensively over the past several decades as a heuristic device for understanding ancient Mesoamerican beliefs. However, some of these interpretations seem to be better founded than others.

The so-called Olmec culture of the Early to Middle Formative Periods (ca. 1500–400 B.C.E.), centered on the Mexican Gulf Coast states of Veracruz and Tabasco, has been conceptualized by many scholars as the “mother culture” of Mesoamerica, the origin of the basic traits shared by all later Middle American civilizations and of an art style diffused from central Mexico to El Salvador and Honduras. More recently, other archaeologists argued that the Olmec were a “sister” culture to their contemporaries and successors. Rather than originating the art style associated with them by champions of the “*cultura madre*” view, they may have produced the finest and most monumental expressions of a pan-Mesoamerican art style which did not originate on the Gulf Coast. Olmec portable stone

carvings frequently depict men who appear to be transforming physically into jaguars, the most common animal ally or alter ego for modern Central and South American shamans. In some of these images, human features predominate, while in others varying mixtures of human and feline traits seem to represent shape shifting in varying degrees of progress. One of these figures, now in the Princeton Art Museum, bears an engraving of a toad on its head, and toad bones occur in refuse at the Olmec site of San Lorenzo. This is further evidence for shamanic practice: *Bufo marinus* and other toad species are a source of potent hallucinogens. The shamanic model, as proposed by Peter Furst, F. Kent Reilly and others, fits the evidence well in this instance, though caution is always required in comparing the visual culture of a Mesoamerican group which has left us no written records with ethnographic data collected thousands of years later and from across wide expanses of North, Central, and South America. Equally intriguing but uncertain are interpretations of the body postures of Olmec portable figures as positions facilitating meditative states and the cultivation of trance.

Olmec monumental reliefs at the sites of La Venta and Chalcatzingo, and paintings at Oxtotitlan, showing elaborately costumed figures emerging from the mouths of monsters, have also been given a shamanic interpretation. Reading backwards, from the beliefs of contemporary Maya shamans and the inferred practices of their Classic Maya predecessors, these saurian, ophidian and/or feline mouths represent symbolic portals into the earth and underworld, or perhaps to the celestial realms. The richly garbed figures are Olmec kings performing the functions of the shaman, in these instances journeying to the spirit world to obtain adequate rainfall and agricultural bounty for their polities. They may be the earliest instances of a conception of otherworldly portals in zoomorphic form that has survived to the present Mesoamerica. The difficulty, however, with readings of this sort is that they are inferences based on chains of extrapolations from the historic to the pre-Hispanic Maya and then back to the Olmec. Even assuming the continuity of use of such motifs, disjunctions in their meaning

might be expected over time and across geographic and linguistic boundaries.

The late Linda Schele used the shamanic beliefs and practices of contemporary Maya as a fruitful analog for comprehending Classic Maya ritual and iconography, like the images of ancestors conjured through "Vision Serpents" by the bloodletting rites of Classic Maya kings. These represent supernatural portals to the realm of the ancestors and are analogous to the supernatural serpents that swallow and excrete contemporary Maya shamans in their initiatory experiences. Similarly, her work led to the identification of a class of supernatural beings represented in Classic Maya art as the spirit alter-egos of Maya rulers, called *wayob* in the accompanying texts. Her work has received considerable support from the ongoing decipherment of Maya glyphs but is not without its critics. These point out, among other things, that the autosacrifice of blood from their tongues and genitals by Maya rulers may not be physiologically conducive to trance states as claimed in Schele's original formulation.

The iconography of ceramic sculpture accompanying burials in the Late Formative to Classic shaft tombs of West Mexico has been interpreted by analogy to the shamanism of the Huichol and other contemporary indigenous groups. The most prominent proponent of this approach, anthropologist Peter Furst, identifies horn-like protrusions on the heads of some anthropomorphic figures as a mark of shamanic status akin to the coiffures of historic Sioux medicine men and the horns of shamanic figures in Asian myths. First interprets the emaciated or skeletal state of some of the humans in West Mexican ceramic effigies as representing forces of renewal rather than death, by analogy to the initiation experiences of contemporary shamans who are stripped of their flesh in visions and reconstructed by the spirits in their new identity as ritual practitioners. (Jill Leslie Furst has used the same complex of imagery as a fruitful heuristic device for interpreting the meaning of skeletal deities in Mixtec manuscripts as gods of fertility and rebirth.) The geographic proximity of these West Mexican sites to the

current territory of the Huichol and other tribes with strong shamanic traditions supports Furst's readings, but again caution is required in generalizing meanings across great expanses of time. Contra Furst, Mark Miller Graham interprets the "horns" of West Mexican tomb figures as conch shells symbolic of rulership. While not dismissing the presence of shamanic themes and imagery in this art tradition, he emphasizes the manipulation of such ideas by pre-Hispanic political elites to maintain their status, over what he criticizes as the ahistorical generalizations about visionary experiences in Furst's writings.

In other instances, the attempt to read ancient Mesoamerican images through a shamanic lens seems strained and stretched. Some scholars seem to interpret every form, material, and function of any given pre-Columbian art object as related to shamanism, as though the culture consisted of little other but such religious practices. A recent catalog of pre-Columbian art from Mesoamerica, lower Central America, and the Andes in the Michael Carlos Museum at Emory University seeks to interpret almost every formal and iconographic feature of portable objects like ceramic vessels in terms of ethnographic observations of shamanism often removed in time by centuries and often by geographical distances of hundreds of miles. Designs on Central American ceramics, for instance, related to the altered perceptions of the shamanic trance; the rattles attached to effigy vessels attempt to evoke the sound of animal allies. All of these interpretations are brilliant and creative. Some may be quite accurate, while others may be stretching the concept of shamanism as a hermeneutic tool for interpreting pre-Columbian art to its limits and beyond. In the present state of knowledge and absence of written records for most of this material, these interpretations are largely unverifiable. There is always the risk of projecting the ethnographic present onto the archaeological past, when, because of the lapse of intervening centuries and the major cultural changes wrought by Christianity and European conquest, ancient beliefs may have been quite distinct from their latter-day descendants in the same region. When

analogies to pre-Columbian material are sought in modern shamanistic complexes as far away from Mesoamerica as the North American Plains and the Amazon, their explanatory value becomes more questionable.

Recently, some Mesoamerican scholars, notably the American art historians Cecelia Klein and Esther Pasztory, have sharply criticized the characterization of pre-Columbian art and religion as shamanic. They point out that most societies described as having shamanistic religions in the ethnographic literature operate on a far less complex level of social organization than the civilizations of Mesoamerica. They question the validity of using a construct developed to explain religious behavior among hunter-gatherers or small villages for understanding Mesoamerican state-level societies, like the Aztec and Maya. In the case of the Aztec at least, it is clear that religious life was dominated not by shamans but by a vast bureaucratic hierarchy of priests, most of who were probably not natural born visionaries. Although the mercurial Aztec deity Tezcatlipoca may have had shamanic origins, he was the patron deity of the Aztec monarchy. For the Classic Maya, hereditary sacred monarchs performed the rites characterized as shamanic—clearly a different social context than most of the behaviors classified as shamanism in other parts of the world. On the other hand, Furst contests these critics' categorization of shamanism as limited to relatively egalitarian hunter-gatherer groups, pointing out the dominance of shamanism in several northern South American agricultural town societies.

Some critics equate the use of shamanism to explain pre-Columbian cosmology and symbolism with the romantic primitivism of the New Age movement and its fetishization of Native American religions. Yet, much of Schele's and others' work on Classic Maya shamanism has been confirmed by—and has stimulated—recent epigraphic work. It appears that the beliefs of modern Native Mesoamericans can serve as springboards for framing hypotheses about the ways of their ancestors, but caution is needed to avoid overspeculation and casting the past in the mold of the present.

Shanghan Lun

Richard Bertschinger

The *Shanghan Lun* (Treatise on Cold-Induced Fevers) by Zhang Zhongjing was written about AD 210. It is the first important practical work in Chinese medicine that has come down to us. The legend is that within a period of 10 years nearly two-thirds of Zhang's village died of illness, mostly from infectious diseases. Zhang, seeing so much suffering, forced himself to find a way to save them, and looked up the ancient prescriptions and read the ancient books. At the end of the third century, after the political turmoil accompanying the breakup of the Han dynasty, the book was reorganized and edited. In the eleventh century, the Song scholar Lin Yi further recompiled and divided it into two sections: the *Shanghan Lun* as we know it today and the *Jingui Yaolue*

Fang Lun (Treatise on the Golden Casket Collection of Prescriptions).

Most admirable in Zhang was his scientific approach to medicine. He berated doctors who used secret remedies to dupe people, saying “what looks magnificent on the surface may be rotten underneath.” He attached great importance to close observation and early treatment of conditions, adjusting the remedies to suit the disease and changing the medicine as the cure progressed. He deplored the frequent use of purgatives. As a mild laxative he prescribed pig’s bile mixed with vinegar poured into the rectum through a ► [bamboo](#) tube. He observed the fluctuation in temperature during fevers, and devised a model for the progression of disease based upon the separation of Yin and Yang into *Shaoyang*, *Taiyang*, *Yangming*, *Shaoyin*, *Taiyin*, and *Jueyin*. This has been a most influential categorization in Chinese medical literature.

Earlier works had recorded the reaction of the pulse to pathological conditions, but Zhang extended his theory to include the pulse’s reaction to the effects of drugs.

About 200 simple herbal medicines were then known, of which the most common were emetics, purgatives, and antipyretics. For instance rhubarb, sodium sulfate, and croton plant were used as purgatives. For reducing fever there was scutellaria, cinnamon bark, ephedra, and bupleurum. As emetics the stalks of various gourds or melons, and parts of the gardenia were recommended. Such remedies are now in use throughout the world. Rhubarb, for instance, was introduced into Europe in the fifteenth century, and imported up to the nineteenth century. The action of ephedra has been mimicked by modern drugs and is invaluable in asthma.

As analgesics and sedatives, various parts of the aconite plant and almond were used. Almond extracts are still used to relieve coughing. Aconite was toxic, but with extreme care it could be useful as a cardiac tonic and nervine. Ginger, licorice, dates, onion roots, and orange peel were used as digestives.

Artificial respiration is mentioned and the use of it in suicides by hanging. In cases of poisoning, water was forced down the victim’s throat to

wash out the stomach – much as in modern hospitals. In diet, Zhang also forbade the use of food derived from animals which had died from disease, and stressed the importance of proper storage and hygiene.

His whole work is a clear example of early scientific method. His manner, most obviously suited to herbal medicine, has been largely adopted by the modern Chinese in their presentation of Chinese traditional medicine. With its differentiation of disease by signs and symptoms, it guides the student into a clear etiology, differentiation of condition, treatment plan, and prescription – whether treatment by acupuncture, herbal medicine, massage, diet, or therapeutic exercise is intended.

Sharaf al-Dīn al-ṭūsī

Jan P. Hogendijk

Little is known about the life of Sharaf al-Dīn al-Muẓaffar ibn Muḥammad ibn al-Muẓaffar al-ṭūsī. He was born in ṭūs (Iran), probably around 1135. He spent part of his life in Syria and Iraq, and died in Iran around 1213. He had a number of pupils, including the famous polymath Kamāl al-Dīn ibn Yūnus.

Sharaf al-Dīn al-ṭūsī was one of the best mathematicians of the Arabic tradition. His most important work is a treatise on cubic equations, in which he develops the theory quite beyond the limits reached by al-Khayyām. The Arabic mathematicians only considered positive coefficients, and they therefore distinguished various types of cubic equations, such as $x^3 + bx = c$, $x^3 + c = bx$, $x^3 = bx + c$, $x^3 + ax^2 = bx + c$, $x^3 + bx = ax^2 + c$, and so on. For all these types, ‘Umar al-Khayyām indicated a geometrical solution of a positive root x (negative and zero roots were not taken into account). For al-Khayyām, the coefficients a , b , c were not in the first place numbers: a was a line segment, b was a rectangle, and c was a parallelepiped. Using these data, al-Khayyām constructed two conic sections, and he supposed that these ► [conics](#) intersected in a point P . He then constructed x by means of P . It is obvious that this procedure only works if point P exists. For some types of cubic equations (for example $x^3 + bx = c$ and $x^3 + bx = c$) it is easily proven that a point P always exists, so the equation always has a root x . For other types of cubic equations (such as $x^3 + c = bx$) P may or may not exist, depending on the coefficients of the equation. The only way in which al-Khayyām could find out whether point P existed was by actually drawing the conic sections, which could be done with limited accuracy (it is unclear whether al-Khayyām ever constructed a root x this way, because the subject seems to have been of theoretical interest only). Thus it was not precisely clear when a cubic equation like $x^3 + c = bx$ had a root.

For the particular case of $x^3 + c = ax^2$, some predecessors of al-Khayyām had shown that a root x exists if and only if $c \leq (4/27)a^3$. Thus these mathematicians knew in advance whether a root existed, and they only needed the conic sections to construct x . Sharaf al-Dīn showed that similar (but much more complicated) conditions exist for all types of cubic equations which do not always have positive roots. He meticulously proved the correctness of these conditions by means of the methods of “geometrical algebra” used by Euclid in Book II of the *Elements*.

He then gave a geometrical construction of the roots x , and (unlike al-Khayyām) a numerical procedure, which could be used to approximate the roots with any desired accuracy. In the theory of cubic equations, no further progress was made until the discovery of the algebraical solution in Italy after 1500.

In addition to his treatise on equations, Sharaf al-Dīn wrote two short works on elementary geometry. He also invented the “linear astrolabe,” consisting of a staff with a plumb line and two cords. The staff contained the markings of the North-South line of an ordinary astrolabe. Although this instrument is easier to construct than an ordinary astrolabe, it does not look nice and it is not user-friendly. Thus it is not surprising that no examples have survived.

Shell Middens of the Coast of Balochistan

Paolo Biagi

Department of Asian and North African Studies,
Ca’ Foscari University – Venice, Venezia, Italy

According to Arrian, the Greek historian, the region that extends west of the Hab River,

which divides Sindh in the east from Las Bela in Balochistan in the west, has been known since the Hellenistic times to have been settled by the Oreitai, an ethnic group similar to the Ichthyophagi (McCrindle, 1973), although no archaeological trace of their presence has ever been recorded during the surveys made in the area (De Cardi, 1983; Khan, 1964, 1979; Raikes, 1967–1968; Stein, 1943). In effect the first traces of prehistoric shellfish eaters were discovered by chance, when Professor A. R. Khan of Karachi University showed me, in his museum, a few decolored specimens of *Terebralia palustris* mangrove shells he had collected a few years before along the shores of a small bay called Daun, some 15 km south of Cape Gadani, in Las Bela province. A brief visit paid to Daun in January 2000 led to the discovery of a few shell middens (Biagi, 2003–2004, 2004, 2013), while

many others were recovered between 2004 and 2008, south of the same bay and on the Pleistocene marine terrace that raises from the beach just to the southeast (Biagi, Fantuzzi, & Franco, 2012). Further surveys conducted along the southeastern coast of Las Bela in the following years have shown that shell middens with different characteristics and variable chronology exist in many places (Fig. 1) among which are Gadani and Phuari Headlands (Biagi, Nisbet, & Girod, 2012–2013) and the shores of Lake Siranda (Biagi, 2011; Biagi, Girod, Nisbet, & Fantuzzi, 2013a; Biagi, Girod, & Nisbet, 2013b). Shell middens are places where the debris from eating shellfish and other food has accumulated over time. They can contain shellfish remains; bones of fish, birds, and land and sea mammals used for food; charcoal from campfires; and tools made from stone, shell, and bone. Shell middens tell us

a lot about Aboriginal activities in the past. The types of shells in a midden can show the type of marine environment that was used and the time of year when Aboriginal people used it (Kristiansen, 2002).

The Balochistan Sites

Daun

As mentioned above, prehistoric shell middens were discovered in three distinct spots around the Bay of Daun and its surroundings, where they cover a roughly rectangular area between $24^{\circ}59'18.08''$ – $25^{\circ}00'27.29''$ N and $66^{\circ}42'19.35''$ – $66^{\circ}43'07.22''$ E (Fig. 2). They are

represented by heaps or scatters of fragmented mangrove shells, mainly *Terebralia palustris*, although specimens of *Telescopium telescopium* and *Anadara uropigmelana* also occur. Among the sites, a special role was undoubtedly paid by shell midden 1 (Fig. 3), on the surface of which 50 pitted crushing stones with pecked round or oval grooves were recorded, most probably anvils used for opening shellfish (Figs. 4, 5, and 6). The site also yielded a few chipped stone artifacts made from both Gadani dark red flint and other varieties of chert most probably derived from a source located in the interior Las Bela. In addition to site 1, site 10 is also unique. Located somewhat far from the others, well sheltered between volcanic rocks, its surface is

Shell Middens of the Coast of Balochistan, Fig. 7 Daun: shell midden Daun 10 photographed from the south

characterized by mangrove gastropods in a very high state of fragmentation (Fig. 7). Narrow bladelet small cores (Fig. 8) and geometric, microlithic chipped stone tools, among which are one lunate and one trapeze, were collected from its surface (Biagi, Fantuzzi, & Franco, 2012, Fig. 12). Other shell middens located further south are sometimes grouped together. Their distance from the present Arabian Sea coast varies from 60 to 700 m (Fig. 9). Seventeen out of 29 sites have been radiocarbon dated mainly from samples of *Terebralia palustris* shells. The analyses yielded very interesting results, which help us follow the environmental changes that took place in the surroundings of the bay between the first half of the seventh and the end of the fifth millennium BP (Fig. 10). They show that Neolithic shellfish gatherers first visited the bay when favorable conditions led to the establishment of mangrove environments. The area was almost uninhabited during the Copper Age and visited again during the Mature Indus Civilization, to be finally abandoned around the end of the Bronze Age (Fig. 11).

Gadani and Phuari Headlands

Gadani is a small promontory, 87 m high, easy to recognize because of the pinkish color of the Parh limestone formations that characterize it (Khan, 1973). The cape is separated from Ras Phuari, some 3.5 km to the south, by a strip that runs in NNE–SSW direction, in the center of which flows a small, seasonal stream called Kunari Dora (Fig. 12). The territory has a complex sedimentary sequence, characterized by Bela Ophiolites (Sarwar, 1992) and Parh limestones (Naseem, Sheikh, & Qadeeruddin, 1996–1997), the latter containing good quality, dark red flint nodules that were exploited in prehistory since the Mesolithic for making tools (Figs. 13, 14, and 15). Prehistoric sites, mainly shell scatters containing a few chipped stone artifacts and potsherds, were discovered on both capes during three brief surveys conducted in 2002, 2011, and 2012 (Biagi, Nisbet, & Girod, 2012–2013). The AMS results obtained from four mangrove (*Terebralia palustris*) and marine (*Purpura panama*) shell samples have shown that both capes were

sporadically settled during the middle of the fifth millennium BP, when mangrove swamps flourished in the area, and the end of the second millennium BP, when the seasonal gathering of marine shellfish had taken place (Fig. 16).

Lake Siranda

Intensive surveys carried out between 2011 and 2013 by the Italian Archaeological Mission have shown the importance of the archaeological region surrounding Lake Siranda, a shallow basin some nine miles long and two miles wide that receives seasonal water from the Watto River and is sometimes filled with summer monsoon rains. Siranda depression, which is considered by some authors a playa remnant of the Sonmiani Lagoon (Snead, 1966, 1969), formed by a gradual recession of the sea (Minchin, 1907), is delimited by sand dunes that elongate in north–south direction along its western side (Snead & Frishman, 1968). Its shores are dotted with prehistoric shell middens that are easy to recognize because of the

presence of mangrove shell fragments, mainly *Telescopium telescopium* and *Terebralia palustris* gastropods. Many sites have been discovered along the southeastern low terrace of the lake. Given that more than 70 shell middens of different shape, size, and age have been so far discovered, we can assume that Siranda was repeatedly visited or temporarily settled for the gathering of shellfish mainly during the Neolithic (Fig. 17). Copper and Bronze Age sites have also been recovered as shown by the results from the AMS dates obtained from 27 middens, which attribute them to a period comprised between the second half of the eighth and the second half of the fifth millennium BP (Fig. 18). Along the lake perimeter, which shows different morphologic characteristics region by region (Fig. 19), shell middens occur as real mounds up to 3 m thick (Fig. 20), small mangrove shell scatters (Figs. 21 and 22), and thin, almost circular sites, up to some 75 m in diameter (Fig. 23). The material culture remains from the Neolithic shell middens consist of chipped stone tools often obtained from Gadani dark red flint,

Shell Middens of the Coast of Balochistan,
Fig. 15 Cape Gadani: dark red Gadani flint natural block and tools on the surface of one of the prehistoric sites

among which are geometric microlithic inserts. They are represented by lunates and isosceles trapezes obtained from microbladelet blanks (Fig. 24). Coarse stone tools were also recovered, among which are lower querns and anvils (Fig. 25), as well as a few net weights. The results of the surveys carried out around the lake show that the depression was a shallow tidal lagoon surrounded by mangroves at least during the Neolithic and Chalcolithic periods. The basin emptied most probably around the end of the Bronze Age when the sea definitively reached the present-day level. At present some of the lake's surfaces are covered with millions of *Melanoides tuberculata* freshwater gastropods (Fig. 26) that might contribute to the interpretation of the events that took place after the retreat of the sea. The AMS dating of a *Melanoides* sample retrieved in situ from a profile close to site

2 (Figs. 16, 27, and 28) yielded the result of 830 ± 30 uncal BP (GrA-57527), a date that marks some important event connected with the freshwater filling of the lake.

Sonari

Sonari is a very important Bronze Age village built on a terrace located at some 25–30 m of altitude west of the Hab River mouth (Fig. 29). The site was discovered by Professor A. R. Khan in the 1970s and never reported in any of his papers. The terrace was revisited in January 2001 (Biagi, 2004) and systematically surveyed in August 2013. Apart from the above Bronze Age fishermen village that consists of rectangular stone structures, a few of which are covered with *Meretrix* marine bivalves (Fig. 30), traces of older shell middens have been recorded on the same terrace, at least one of which is to be attributed to the Neolithic because of the presence of characteristic lunate microliths. The Bronze Age village has been radiocarbon dated to dated to 4780 ± 60 uncal BP (GrA-59839) and 4850 ± 60 uncal BP (GrA-59837) from two specimens of *Meretrix* marine bivalves (Biagi & Nisbet, 2014). From its surface come many net sinker (Fig. 31) ground stone tools, among which is a saddled lower quern, and a few potsherds.

Considerations

The data presented above show that the first Holocene peopling of Las Bela coast took place during the last centuries of the eighth millennium BP, when most of the shores of the Arabian Sea and the Persian/Arabian Gulf started to be settled at least temporarily by fishers and shellfish gatherers who exploited the resources available from specialized mangrove environments (Biagi, 2008; Boivin & Fuller, 2009). The discovery of shell middens around the shores of Lake Siranda is of major importance because it helps us define the geographic and environmental characteristics of some traits of the coastal landscape settled by the earliest Neolithic inhabitants of the

northwestern corner of the Indian Ocean and compare it with the information available from other regions of the Arabian Sea, Oman, for example (Berger et al., 2013). In both countries the Neolithic coastal peopling seems to have followed the same trend, with fisher–gatherers exploiting well-developed mangrove environments along the shores of lagoons that started to dissect just after the retreat of the ocean waters that took place in the Bronze Age.

Acknowledgment The author is very grateful to Dr. R. Nisbet and A. Girod, who took part in the Las Bela surveys, for providing Figures 11, 16 and 30 (R.N.) and for the identification of the marine shells (A.G.), and to Dr. T. Fantuzzi for the calibration of the radiocarbon dates.

Shen Guo

Fabrizio Pregadio

The Chinese scholar, statesman, and scientist Shen Guo was born in 1031 in present-day Hangzhou (Zhejiang). Born into a family of gentry, he entered civil service in 1054, holding minor posts in different provinces where he distinguished himself in a series of projects involving water control. After passing the national doctoral examinations in 1063 he moved to the capital, Kaifeng, and in 1072 was named Director of the Astronomy Bureau. In that position he reorganised the Bureau, planned a program of astronomical observations, and devised a calendar that was effective from 1075 to 1092. His work as astronomer alternated with missions to the provinces, where he was again able to display his skills in hydraulic engineering. The relief maps he made in 1074 (using wooden plates, sawdust impregnated with glue, and melted wax) are among the most celebrated specimens of Chinese cartography.

The whole of Shen's career was influenced by his partnership with Wang Anshi (1021–1086), the leader of the “New Policies” (*xinfu*) group which advocated a reform program aimed at strengthening the central government, regulating finances by law, and exploiting nature for the state's benefit. Shen's memorials to Emperor Shenzong (r. 1067–1084) on a variety of subjects – including military strategy and tax levies – won approbation in a dozen instances.

In a related development, Shen was sent as an envoy to the Khitan court in 1075, and, in a feat of diplomacy, was able to put at least a temporary end to the borderland skirmishes and the repeated Khitan claims of Chinese land.

Following his diplomatic victory, Shen Guo was appointed Finance Commissioner in 1077, but that very year also marked the turning point of his political fortune. The opponents of the “New Policies” had succeeded in pressing Wang Anshi into retirement. Shen was in turn charged with duplicity in his fiscal policies, and demoted. Three years later, partially rehabilitated, he was sent to the Shenxi province as Commissioner for Prefectural and Military Affairs. In 1081 he obtained an important military victory against the Tanguts. One year later, however, he was held responsible for the disastrous defeat that the Chinese troops suffered in the same area, and put on probation.

Shen spent the following years completing a map of the territories under Chinese control, for which he was commissioned by the Emperor in 1076. When he submitted it to the throne in 1088, his rewards included the right of choosing his residence. He thus moved to the “Dream Brook,” a garden estate that he had bought some years earlier near present-day Zhenjiang (Jiangsu), and devoted most of his time to writing, until his death in 1095.

Shen Guo’s writings include treatises on administration, military strategy, astronomy, medicine, poetry, ritual, and several other subjects. His best known work, entitled after the name of his retreat, is the *Mengqi bitan* (Brush Talks from Dream Brook). Written in the final years of his life, and supplemented by two shorter works probably published posthumously, it consists of about 500 jottings on disparate matters, usually short and organized into topics. The original edition was in 30 chapters, of which 26 are extant. Of special importance from the point of view of the history of science are the sections pertaining to mathematics, astronomy, meteorology, optics, physics, geology, and medicine.

To give only a few examples, chosen among the more important parts of his work but clearly inadequate to reflect the richness of its contents,

in the field of astronomy Shen Guo described solar and lunar eclipses, studied the moon phases, and provided reasons for the apparent planetary motions. During his appointment as Director of the Astronomy Bureau, moreover, he modified the design of the sighting tube pointing to the Pole Star in the armillary sphere. In the field of geology he recognized the origin of fossils, and gave an account of the role of erosion. Other jottings are concerned with magnetism, the production of inverted images on concave mirrors, the formation of rainbows, the fall of a meteorite, and the process of printing. All this adds to his skills in cartography and hydraulic engineering.

As several scholars have remarked, Shen Guo never attempted to organize his observations into a general theory. His work is, in many ways, the product of an exceptionally bright mind, motivated by a sharp curiosity in observing, understanding, and describing whatever phenomenon aroused his interest. This was by no means limited to natural processes or to man-made techniques. One chapter of the *Mengqi bitan* deals with supernatural matters, which the author treats with the same sympathy he accords to the other fields that attracted his attention. For a proper assessment of Shen Guo’s personality and production, the “scientific” features of his works should be evaluated without neglecting their own context or disregarding other features which we might label as “unscientific.”

From another point of view, Shen Guo reveals the short-comings inherent in the equation between Daoism and scientific progress on one hand, and Confucianism and scientific conservatism on the other, which has influenced some recent work in the history of Chinese science. While Daoists were not interested in nature per se (nature was before all an “image,” *xiang*, of the absolute principle, the *Dao*), Shen Guo shows that interest in natural facts could be, and indeed was, actively pursued by a “Confucian” scholar and state administrator.

Shibukawa Harumi

Nakayama Shigeru

Shibukawa Harumi (1639–1715) was a Japanese astronomer and calendar reformer whose distinguished service in calendar reform led to his appointment in 1685 as official astronomer.

The Chinese lunisolar Xuan-ming calendar, adopted in Japan in 862, had not been reformed for more than 800 years. Over the centuries the discrepancy in the length of a solar year had increased so that by Harumi's time there was a 2-day delay in the winter solstice.

With able diplomatic skill, Harumi urged that the Shogunate government undertake calendar reform. In 1669 he began conducting astronomical observations, probably the first systematic observations made in Japan. Following the procedures of traditional Chinese astronomy, he set up a gnomon and measured the lengths of shadows at various points before and after the

winter solstice, in order to calculate the time of occurrence. He was especially interested in the Shoushi calendar of the Yuan dynasty (1279–1368), a crowning achievement of calendrical astronomy adopted in China in 1282, and his observations were based upon its methods.

In his reference to Western theories, Harumi based his information on scanty sources and came to regard Western astronomers as “barbarians who may have theories but cannot prove methods.” It is regrettable that sufficient material for evaluating Western theories was not available to him.

During the eighteenth century Japanese astronomy altered its orientation from China to the West. Harumi belonged to the first generation of astronomers who, with only limited knowledge of Western astronomy, began evaluating the merits of both systems.

Ship- and Boatbuilding in Ancient Egypt

Samuel Mark

Maritime Studies Program, Texas A&M University Galveston Campus, Galveston, TX, USA

We lack evidence of construction techniques for the earliest Egyptian vessels, but in the Naqada II period (c.3500–3200 BC), there is a change in iconography from boats with a flat profile interpreted as papyrus rafts to “sickle-shaped” boats (Fig. 1). These boats must have been built from wood as most of the hull is out of the water, and it coincides with the earliest evidence of

wooden planks in graves and copper woodworking tools (Mark, 2013a).

In the second half of this period appear depictions of the earliest known sailboats, an especially important invention because consistent north winds allowed boats to sail upstream for c.1,200 km, and its appearance coincides with the earliest evidence of bulk cargoes transported in pottery containers over long distances. Sailboats may also have influenced the development of the Egyptian state. During the Naqada III period (c.3200–3000 BC), Upper Egyptian sites appear in Lower Egypt probably to control trade. An

uninhabited region of c.250 km separated the two regions, but sailboats allowed for the establishment, resupply, and support of colonies or armies, leading to the eventual unification of Egypt. The importance and effectiveness of the Nile as a highway is emphasized by the lack of a well-developed system of roads before the Roman period (Mark, 2013a).

Early Dynastic and Old Kingdom Vessels

A few fragmentary boats have been studied from the First Dynasty, but an excellent example survives from the reign of Khufu (c.2566 BC) in the Fourth Dynasty. It is $c.43.63 \times 5.66 \times 1.8$ m and built primarily of c.38 t of Lebanese cedar (*Cedrus libani*) (henceforth cedar). The planking is very thick (12–15 cm), long (7–23 m), and wide (widest c.70 cm) with joggled edges to help lock them together (Fig. 2) (for this vessel, see Lipke (1984), Ward (2000), and Mark (2009, 2011)). The technique of overlapping planking is seen as early as the First Dynasty in the Abu

Ship- and Boatbuilding in Ancient Egypt, Fig. 1 Graffito of a sickle-shaped sailboat (After Červíček (1974), Fig. 156)

Ship- and Boatbuilding in Ancient Egypt, Fig. 2 Planking plan (After a photograph from the Paul Lipke Collection http://inadiscover.com/projects/all/africa/cheops-khufu_i_boat_documentation/photo_gallery-1/)

Rawash boat (c.2970 BC), but planking is irregularly shaped and lacks the numerous joggles seen in the Khufu I planking probably because it was smaller and was built with shorter, local woods with more flaws.

Hull planks in the Khufu I vessel are edge-joined with mortise-and-tenon joints (Figs. 2 and 3A). Tenons are sidder (*Ziziphus spina-christi*), a deciduous wood, while planking is typically a coniferous wood because when wet, coniferous planking swells around tenons for a tighter fit but deciduous tenons swell less, keeping planking from splitting. Egyptian boatwrights probably adapted this joint to boatbuilding so vessels could be broken down and rebuilt.

Once fitted together hull planks were lashed in place by 105 transverse plaited straps that ran through rows of V-shaped lashing holes from port to starboard sides where they were probably tied off to crossbeams. Their size (c.7 × 2 cm) and placement (spaced c.25 cm longitudinally and c.10 cm transversely) appear to be standardized (Figs. 2 and 3B). Transverse lashing holes are on the Abu Rawash boat and on the First Dynasty Abydos BG 10 boat.

Most transverse lashings run over seam battens, but an unknown number passed under

battens and either through plank edges or pierced exterior surfaces to reinforce planking under considerable stress (Fig. 3C). Battens had four functions: tightening lashings, maintaining watertightness by pressing down on seams, distributing pressure on seams uniformly between widely spaced transverse lashings, and large battens completely covered scarfs, adding structural reinforcement. Before battens were fitted, an organic material called wadding may have been laid on interior seams that were slightly open (Fig. 3D). If so, when lashings were tightened, battens would force wadding into seams increasing watertightness.

Hull planks were lashed to 66 crossbeams. Only the lengths were measured as crossbeam sizes and shapes were standardized. The widest is 30 × 10 cm, those forward of it are 10 × 10 cm, those directly aft are 12 × 12 cm, and those aft of the deckhouse are 11 × 11 cm. The widest crossbeam either supported a mast or reinforced the main hatch or both.

These features indicate this hull was designed to be broken down and rebuilt, but they produced a weaker hull. Longitudinal girders were therefore needed at deck level. Side girders (11 cm × 26 cm × c.26 m) were notched and fitted on top of the middle 48 crossbeams and then lashed to poles (c.10 cm in diameter, c.7 m long) below crossbeams (Fig. 3E) to allow further tightening. Side girders were designed to resist longitudinal forces and were also reported on the First Dynasty 3506 boat at Saqqara.

A central girder of the same dimensions was notched and fitted to the underside of the same 48 crossbeams (Fig. 3F) and primarily resisted lateral forces from flexing crossbeams. It also absorbed longitudinal stress and therefore was supported by 16 stanchions fitted on top of 16 frames, 8 full length and 8 three quarters, each carved from a naturally curving timber (Fig. 3G) and notched to fit over battens and then lashed in place. Frames were too widely spaced (c.170 cm) and too small (c.7 cm sided (wide), c.12–20 cm molded (high)) in relation to the hull planks (c.12–15 cm thick) to support planking. Instead, they uniformly spread downward forces from the central girder across a hull.

Ship- and Boatbuilding in Ancient Egypt, Fig. 3 Half-breadth of the Khufu I vessel (After Lipke (1984), Fig. 48 and photographs from the Paul Lipke Collection)

Ship- and Boatbuilding in Ancient Egypt,

Fig. 4 Sailboat from the Tomb of Ti (After Steindorff (1913), pl. 78)

The ends of this hull were tied together by a complex combination of overlapping planking with beveled edges and scarfs designed to support papyrus decorations. In contrast, most Nile boats before the Sixth Dynasty were built with flat transoms (Fig. 4).

Cedar deck panels were prefabricated, ranging in size from .32 to 9.19 m². The smallest panels directly forward of the deckhouse were easily removable, and the one aft of the widest cross-beam was large enough to take a mast. Reliefs from the reign of Sahure depict the same type of craft under sail, and the location of the mast is close to the location of the wide crossbeam on the Khufu I vessel (Fig. 5). Masts are bipod with tall, tapering sails. The lower spar sits on the hull to reduce weight. Single pole masts are only on the smallest vessels, but the lower spar still rests on deck (Fig. 6), suggesting structural limitations in hulls. Changes in mast and sail from predynastic times suggest sails became too large and heavy for hulls to support them with only pole masts (Figs. 1, 4, 5, and 6).

The cedar deckhouse (c.9 m long) was also prefabricated and probably standardized (Fig. 7), allowing it to be constructed at another location, like the deck panels. A prefabricated deckhouse

may have been on the First Dynasty Saqqara 3506 boat.

Finally, this vessel was steered with multiple pairs of quarter rudders. At present only one pair of quarter rudders is outfitted on this vessel and the other five pairs are mounted as oars (Fig. 7), but they are too long (c.6.5–8.5 m long) and too heavy (smallest 57.15 kg) for oars. Furthermore, contemporaneous vessels portrayed on reliefs have multiple sets of quarter rudders (Figs. 4 and 5), except the smallest boats (Fig. 6). Only one line secured each rudder with the lower end attached above the blades and the upper end wrapped around the loom near deck level and then secured to a grommet (Figs. 4, 5, and 6). It supported a rudder's weight and acted as a fulcrum around which a rudder was rotated. Oars were mounted in a similar fashion and sat in notches cut into side girders.

The number of quarter rudders outfitted on a vessel was dictated by its size and speed. Reliefs from the Fifth Dynasty Tomb of Ti portray sailboats rowed, paddled, and at rest with two or three pairs of rudders while the same vessels under sail typically have four or five pairs. Sahure's royal sailboat is the largest with 13 pairs while smaller escort sailboats have four

or five pairs (Fig. 5). As the Khufu I vessel has six pairs, it was the same size as Sahure's escort sailboats or slightly larger. The Palermo Stone states that Sneferu (c.2613–2589 BC) had a vessel 100 cubits (c.52 m) long, which is a reasonable length for Sahure's royal sailboat. Sahure's sailboats are so large that men on deck-houses used U-shaped devices to transmit orders from lookout to helmsman (Fig. 5) while none were needed on smaller sailboats (Fig. 4) (See Mark, 2012b, 2013b).

This is a sophisticated method of construction that appears to have been perfected no later than the First Dynasty, and it “must have been standard maritime technology in ancient Egypt” (Steffy, 1994, p. 28). The only substantial ship timber from the Old Kingdom is a single naturally curving frame notched to fit over battens from the Red Sea port of Wadi al-Jarf, dating to Khufu's reign (Tallet, 2012, Fig. 20).

Ship reliefs from Sahure's reign portray Mediterranean ships, and features on them are consistent with structural elements on the Khufu I vessel, including very long hull planks with long, rolling scarfs. At the ends of some scarfs are small rectangles consistent with the external lashings on the Khufu I hull, suggesting transverse lashings (Fig. 8). Other exterior hull lashings suggest a reliance on lashings over timbers. Longitudinal lashing reinforced crossbeams while vertical lashings at bow and stern suggest a complex system of lashings and joinery to tie the ends together as on the Khufu I vessel. Since similar lashings were used on Nile workboats (Fig. 9), shipbuilding techniques were probably adapted from them, and Mediterranean ships were prefabricated and designed to be broken down and rebuilt rather easily (for this discussion, see Mark, 2014).

Ship- and Boatbuilding in Ancient Egypt, Fig. 9 Nile cargo boat (From Verner (1977), pl. 10, pg. 187 With kind permission of the Czech Institute of Egyptology)

Ship- and Boatbuilding in Ancient Egypt, Fig. 10 Unas' stone carriers (After Selim Hassan (1954), Fig. 1)

Ship- and Boatbuilding in Ancient Egypt, Fig. 11 Reconstruction of a Punt ship (After El Awady (2009), pl. 5)

Blade-shaped objects (henceforth “blades”) depicted at the ends of ships and Nile stone carriers, which carried the greatest weights, were structural timbers because as weights increased, blades were added. A stone carrier carrying one sarcophagus, as well as all ships, was outfitted with one blade, while stone carriers carrying two larger stone columns were outfitted with eight blades (Fig. 10). Before the reign of Unas (c.2375–2345 BC), all blades sat inboard of hull planking; thus it was during his reign that a stem and a stern post were first developed.

Sahure's Punt ships are smaller adaptations because they had to be broken down and carried to the Red Sea. When both ships are scaled to the same length, the Punt ship is shallower by two plank widths amidships (Figs. 8 and 11). Although both have bipod masts, the mast on the Mediterranean ship is heavier as it has more and larger pieces with more fasteners, and it rests in one gallows, while the Punt ship's mast is so light both ends were stowed on gallows and was similar to masts on boats (Fig. 12) which were designed for the relatively gentle north winds on

Ship- and Boatbuilding in Ancient Egypt, Fig. 12 Riverboat (After El Awady (2009), pl. 5)

the Nile instead of the “notorious” winds and gales on the Red Sea.

Moreover, each ship has a hogging truss, a heavy cable running from bow to stern (Figs. 8 and 11). It is a primary structural element to what is typically described as a weakly constructed hull, compensating for a flat bottom, no keel, and a lack of internal timbers. This is an oversimplification because a Chinese Kiangsu trader had these features but no hogging truss. Instead, trusses were probably required because Egyptian ships were designed to be broken down and rebuilt, resulting in an inherently weak hull unable to take additional stresses while at sea.

A truss also indicates a ship’s size. It is waist high on Punt ships and is supported by only one stanchion, while on Mediterranean ships, it is shoulder high and supported by three stanchions. If it parted, structural failure of a hull would follow. A forked stanchion located at the bow of each ship was probably used to raise the mast. On the Punt ship, it was lashed to the truss but not on the Mediterranean ship (Figs. 8A and 11A). Every use of it on the Punt ship would pull against and chafe a truss, fraying and weakening it over time. Securing it in this manner was a calculated risk taken by shipwrights to keeping weight to a minimum.

Punt is believed to have been located between present-day northern Eritrea to southern Somalia for one-way voyages from 1,300 to 2,200 km. Even for Mediterranean ships, this would be a long voyage in notorious waters, lacking harbors for major repairs, but shipwrights could not use large planks and frames as on the Khufu I vessel or Mediterranean ships because they could not be transported to the Red Sea. Thus,

shipwrights were forced to design small and light ships while taking a number of calculated structural risks.

While prefabrication was required for Punt ships, it was not for Nile or Mediterranean vessels. Prefabricated vessels, regardless of size or function, allowed for an unprecedented maintenance of hulls, extending their working life, and provided the most efficient method of recycling wood. Also, standardization was as important because it reduced waste (See Mark, 2012a, 2014).

Changes in Technology

At the beginning of the reign of Unas and through the end of the Old Kingdom, a number of changes were made to vessels. A ship depicted on Unas’ causeway lacks most external lashings while blades are now a stem and stern post (Fig. 13), producing a stronger hull. A stem is also depicted at the bow of his stone carrier (Fig. 10). The height of hogging trusses with only one stanchion suggests Unas’ ship is similar in size to Sahure’s Punt ship (Figs. 11 and 13), but previously cited features along with a larger, heavier tripod mast with only one gallows indicate a heavier, stronger hull. Moreover, the earliest known tillers are outfitted on rudders of workboats, making them more efficient and reducing their number.

By the end of the reign of Pepi II (c.2278–2184 BC), older boat types with bipod masts and a pair of quarter rudders are seen for the last time, but even these appear larger and heavier. They are replaced with a vessel common in the Middle Kingdom with only a pole mast and

Ship- and Boatbuilding in Ancient Egypt, Fig. 13 Unas' ships (After Hassan (1954), Fig. 2)

Ship- and Boatbuilding in Ancient Egypt, Fig. 14 Sailboats from the reign of Pepi II (After Blackman (1953), pl. 22)

a single stern rudder fitted on a stanchion (Fig. 14).

Middle Kingdom

On boat models of this new hull, bulwarks replaced side girders, while a central girder was still used on larger vessels or vessels outfitted with masts. Stern rudders were now standard except on ceremonial boats or boats with stern decorations while ships always carried a pair of quarter rudders in case one broke.

The same philosophy of construction continued. Hull planks from a workboat from Lisht (c.1950 BC) were thick, short, and irregularly shaped and were overlapped. They were edge-joined with a combination of single and parallel mortise-and-tenon joints secured with woven straps in L-shaped holes (c.6.5 cm W; 5 cm D; 1 cm T) but have single instead of transverse lashings. Parallel joints are an indication of the heavier loads these boats carried (see Ward, 2000).

At the port of Ayn Soukhna (Sukhna) on the Gulf of Suez, hull plankings of two ships interpreted as c.13.5–15 m long were found in two caverns (G2 and G9). Plank lengths for both ranged from 2.35 to 6.4 m long. In cavern G2 planks are 28–44 cm wide and 9.5–13 cm thick, while in cavern G9 they are wider 30–40 cm with some 50 cm and one 70 cm and were thicker (11–13 cm). They also appear to have been sawn into flat planks (Pomey, 2012). If so they must have been bent to shape, as on the Khufu I vessel, instead of the prevailing belief they were carved to shape, which would have been very wasteful of timber. For each ship only one hull extremity survived, while the opposite end and all crossbeams, decking, and deck cabin were completely destroyed in the fire that carbonized these planks (Pomey, 2012). Egyptian ships, however, lacked cabins, and instead of two separate ships, there may have been only one ship c.27–30 m long with the narrower forward end in cavern G2 and the wider aft end in cavern G9. If so, the missing timbers may have been stowed in different caverns.

Ship- and Boatbuilding in Ancient Egypt, Fig. 15 Lisht bulkhead (After Ward (2000), Fig. 70)

Planking shapes are similar to those seen on the four Dahshur boats described below. This does not mean these ships were modified Nile boats. Instead, Egyptian craftsmen probably had similar planking plans for cedar and different ones for local woods to efficiently use each type of timber, reducing waste. Like the Lisht timbers, hull planks were edge-joined with mortise-and-tenon joints, but larger planks had a parallel row and smaller planks a single row of them. Planks were secured with straps laced through the same L-shaped holes. Pegs appear to be secondary fastenings but their function and frequency are not clear (Pomey, 2012).

Fragmentary remains of Punt ships were found at the harbor site of Mersa/Wadi Gawasis. Planks are thicker (6.5–22.5 cm) with only parallel rows of mortise-and-tenon joints, suggesting larger ships, some 30 m long (Ward & Zazzaro, 2010a, 2010b), but this estimate is based on two Ayn Soukhna ships, each being 13.5–15 m long. If there is only one ship, Punt ships may have been considerably larger.

According to the *Tale of the Shipwrecked Sailor* (henceforth the *Tale*, a Middle Kingdom story of an Ancient Egyptian voyage to the King's mines), a Red Sea ship was 120 cubits (c.62 m) long and 40 cubits (c.21 m) at the beam for a 3:1 length-to-breadth ratio, indicating a beamy ship that would be expected for a cargo ship only able to make one voyage per year. Since craftsmen could build vessels c.52 m long as early as the reign of Sneferu, a ship 62 m long would not be difficult; the difficulty would be

moving it to the Red Sea. Bulkheads may have allowed this feat. Timbers found at Lisht (c. 1950 BC) appear to have been part of a bulkhead, consisting of short, thick overlapping timbers joined with mortise-and-tenon joints and lashings in L-shaped holes. It was also designed to secure a large longitudinal timber (Fig. 15) (Ward, 2000). An advantage to using bulkheads to replace naturally curving frames would be ease of transport since bulkheads could be disassembled, and they would produce considerably stronger hulls. The longest hull plank at Ayn Soukhna was 6.4 m long while the shortest plank on the Khufu I vessel was c.7 m long. Thus, Egyptians must have developed a technique to build large ships from smaller pieces of wood.

According to an inscription from Mersa/Wadi Gawasis, one expedition required 3,765 men, which included 3,200 soldiers and 500 sailors (Fattovich & Bard, 2012). In the *Tale* above the ship had 120 sailors. Thus, four ships with a crew of 125 are consistent with the ship in the *Tale*.

Four nearly complete cedar boats (9.25–9.92 m long) were recovered near the pyramid of Senusret III (c.1978–1941 BC) at Dahshur. They have heavy, thick planking edges joined with mortise-and-tenon joints and overlapping planking (Fig. 16). Through-beams, like those found at Mersa/Wadi Gawasis, are another structural improvement, but instead of closely spaced L-shaped lashings, boatwrights used widely spaced dovetail joints, which some believe were the original type of joint while another interpretation is that the original lashing

Ship- and Boatbuilding in Ancient Egypt,

Fig. 16 Dahshur boat 4925 (After Landström (1970), Fig. 275)

Ship- and Boatbuilding in Ancient Egypt, Fig. 17 Hatshepsut's Punt ship (After Naville (1898a), pl. 73)

holes were recut as dovetail joints by the discoverers (see respectively Creasman (2010) and Ward, (2000)). Regardless of type, they appear to be too shallow and narrow, especially across the seam (c.15 cm L, c.3 cm W at seam, 2 cm D), and too widely spaced (c.80–100 cm, Khufu I vessel c.25 cm) to have been a standard fastening system on working Nile boats. Moreover, the consistent standardization in Egyptian boat- and shipbuilding to efficiently use, maintain, and recycle timbers suggests it was unlikely a unique fastening system was used only on these boats, especially since deeper L-shaped lashing holes (c.5 cm D) with wide woven straps (c.6.5 cm W) used on the Lisht and Ayn Soukhna timbers would produce very sturdy vessels. The only advantage to these dovetail joints or original small lashings is both could be fashioned faster, especially if a king suddenly died. If built for burial, these boats would only need to be structurally sound enough for transportation to the burial site. There are parallels. The BG 10 boat at Abydos was a symbolic boat held together by lashings, plaster, and the brick tomb, while a number of structural features on the Khufu I vessel also suggest it was rushed to completion, such as recycled framing. Evidence of a rush to completion is seen in drawings of Cairo boat 4925 by Reisner (1913, Fig. 313) and later by Landström (1970, Fig. 275). Dovetail joints are

missing along one seam for a length of c.3.5 m (Fig. 16A, B). The other three Dahshur boats have two or three joints along this same seam, indicating it is structurally unsound for continuous use.

New Kingdom

Hatshepsut's (c.1473–1458) temple at Deir el-Bahri has reliefs depicting five Punt ships that appear larger than Sahure's Mediterranean ships. The hogging truss is above the heads of rowers (cf. Figs. 8, 11, and 17) and supported by four stanchions of equal height to maintaining a maximum height over a greater percentage of the hull, suggesting a considerably larger ship. The number of stanchions is important because when a truss was tightened and the ends of a ship were pulled up, forces increased on each stanchion. As ships became larger and heavier, more stanchions were required to distribute this increasing force more evenly throughout a hull. If these ships, as well as Middle Kingdom Punt ships, were the size of the ship in the *Tale*, there probably was no difference between Mediterranean and Punt ships, allowing for a greater degree of standardization and no more calculated risks to reduce weight (Mark, 2014).

Ship- and Boatbuilding in Ancient Egypt, Fig. 18 Hatshepsut's obelisk carrier (After Naville (1898b), pl. 154)

The largest known Nile barge is also depicted at Deir el-Bahri, and it carries two obelisks end to end (Fig. 18). Hatshepsut's two shortest obelisks, c.30 m each, would require a barge c.84 m long, but her two highest obelisks, c.57 m high, would require one c.140 m long. Some believe it was simply impossible to build such a large barge and obelisks were side by side. They were depicted end to end to show both obelisks. So far no substantive structural arguments have been made to support this belief. Moreover, Ineni describes how he oversaw the construction of a barge built with local sycamore 120 cubits (c.62 m) long to carry two obelisks for Thutmose I, Hatshepsut's father (see Landström 1970). His only surviving obelisk is 20 m high, and based on the above proportions, a barge 55 m long would be required to carry both end to end, which is consistent with Ineni's boast. Thus very large barges were being built especially when compared to Unas' barges (cf. Figs. 10 and 18).

Although the Egyptians based their construction techniques on standardization to efficiently use timber resources (see Ward, 2000), which promotes conservatism, they were also employed as problem solvers. Egypt was a wealthy and centralized state, which could more easily absorb losses in time and resources than could other ancient societies. Also, Egyptian craftsmen built a wider range of vessels, and if the king demanded a specific vessel from a barge to a ship, they would have both the time, resources, and experience to do so. Regardless, Hatshepsut's reliefs suggest a continuation of a trend that may have begun as early as the

reign of Unas, building larger, stronger vessels with smaller pieces of timber (See Mark, 2012a).

Based on iconography, two technical innovations appeared in the New Kingdom. One was the brailed sail (see Wachsmann, 1998), which lacked a lower spar. Instead, parallel lines were sewn along the lower edge of a sail then threaded through lead rings sewn on the face of it. They then passed over the upper spar and back to the helmsman (Fig. 19). A helmsman could manipulate the shape and area of a sail by pulling on different brails to take advantage of different types of wind. It was so efficient it was the standard sail configuration for the Greeks and Romans.

A second innovation was the construction of vessels with pegged mortise-and-tenon joinery as a primary fastening system for hull planking (Wachsmann, 1998). It was the standard technique used to build vessels by the Canaanites, Greeks, and Romans. Yet, to adopt this new system required a change in the basic philosophy of Egyptian vessel construction. At least as early as the First Dynasty, all vessels were designed to be broken down and rebuilt, but this is impossible when planking is built with pegged mortise-and-tenon joinery. The degree of preventative maintenance was greatly reduced, shortening a vessel's life, and even recycling becomes far less efficient. Why and when they made this change and how widely it was used to build different types of vessels is unknown. Their earliest known ships built with them as primary hull fasteners were found at the Egyptian port of Thonis-Heracleion, dating to the sixth century BC (Fabre & Goddio, 2013), but even later

Ship- and Boatbuilding in Ancient Egypt, Fig. 19 Brailed sail

Herodotus (2.96) (c.484–425 BC) describes a boat built using the older method. If pegged mortise-and-tenon joinery was used to build vessels during the New Kingdom as iconography suggests, it was probably limited to specific projects or types of vessels needing extra hull rigidity.

Shipbuilding in Bengal

Indrajit Ray

Department of Commerce, University of North Bengal (on lien), Darjeeling, West Bengal, India
Cooch Behar Panchanan Barma University,
Cooch Behar, West Bengal, India

Shipbuilding is an ancient art in Bengal. Ancient temple sculptures in Java testify about various kinds of ships “the people of Lower Bengal built and used in sailing to Ceylon, Java, Sumatra and Japan in pursuits of their colonizing ambition, commercial interests, and artistic and religious missions” (Mookerji, 1912, p. 156). The developed state of this art enabled its products to get access to distant markets. It caused, as Adam Smith believes, a division of labor in the society and thus ushered in its ancient economic prosperity. The art survived through the Middle Ages so that the Emperor Akbar (1556–1605) could have maintained a flotilla of 3,000 vessels with headquarters at Dacca (now in Bangladesh). In the early seventeenth century, the Bengal flotilla consisted of 4,000–5,000 ships, similar to the Chinese or Arabian *junks*, at 400–600 t each. The mercantile tonnage was also substantial, roughly about 207,500 t in the sixteenth–seventeenth centuries, as against the Dutch mercantile tonnage of 450,000–550,000 in 1630. The industry, however, eclipsed with the Europeans’ monopolization in the Indian Ocean trade but was revived again under the British entrepreneurship in the last quarter of the eighteenth century. Since the wooden ships still prevailed, Bengal’s traditional knowledge and expertise could be explored to give the industry a very competitive edge in international outlets.

Types of Ancient Ships

A ship is a large vessel that can navigate in deep seas. Technically, it was first defined as a vehicle

that carried at least three masts with a square sail. In ancient India, many such ships were constructed to meet the needs of defense as well as a means of commerce. From the standpoint of their physical properties, they were categorized as *Dīrghā* (longer ones) and *Unnatā* (taller ones). As many as ten types of ship belonged to the former category and five to the latter. In cubits, the length, breadth, and height were, for the former, (i) *Dīrghikā* ($32 \times 4 \times 3\frac{1}{5}$), (ii) *Taranī* ($48 \times 6 \times 4\frac{4}{5}$), (iii) *Lolā* ($64 \times 8 \times 6\frac{2}{5}$), (iv) *Gatvarā* ($80 \times 10 \times 8$), (v) *Gāminī* ($96 \times 12 \times 9\frac{2}{5}$), (vi) *Tarī* ($112 \times 14 \times 11\frac{1}{5}$), (vii) *Jangātā* ($128 \times 16 \times 12\frac{4}{5}$), (viii) *Plābīnī* ($144 \times 18 \times 14\frac{2}{5}$), (ix) *Dhārīnī* ($160 \times 20 \times 16$), and (x) *Begīnī* ($176 \times 22 \times 17\frac{3}{5}$), and, for the latter, (a) *Ūrddhvā* ($32 \times 16 \times 16$), (b) *Anūrddhavā* ($48 \times 24 \times 24$), (c) *Svarnamukhī* ($64 \times 32 \times 32$), (d) *Garbīnī* ($80 \times 40 \times 40$), and (e) *Mantharā* ($96 \times 48 \times 48$). As seafaring vessels, contemporary sources underscore the efficiency of (i), (ii), (ix), and (x) in the former category and (a) and (c) in the latter.

Two things should be noted in this context. Firstly, the concept of boat gave rise to the art of shipbuilding that extended it in every dimension – length, breadth, and height – by way of suitable planking in different directions, as well as through the innovation of riggings. Though its length could be greatly enlarged in different civilizations, the extension of width and height posed a serious challenge elsewhere in the contemporary world. The Roman galley, for example, which was driven by 2–3 banks of rowers on each side, ran 100–150 ft in length but only 10–15 ft in width. Even in the mid-nineteenth century when the wooden ship attained the peak of its prosperity, the width could not be significantly augmented. Thus, for example, the clippers like *Ariel* (UK built, 1865), *Donald McKay* (US built, 1855), and *Dreadnought* (US built, 1853) had respective dimensions of $197\frac{1}{2} \times 33\frac{9}{10} \times 21$, $266 \times 46\frac{1}{4} \times 29\frac{5}{12}$, and $212 \times 41\frac{1}{2} \times 26\frac{1}{2}$, all in feet. In contrast, ancient shipbuilders in India constructed vessels by 60–72 ft in width (taking 1 cubit = $1\frac{1}{2}$ feet). Both length and height wise

also, Indian ships were substantial, running up to 364 and 72 ft, respectively. Secondly, for the taller ships (*Unnatā*), a given proportion was always maintained among different sides for the sake of stability in deep seas. For such ships, the width always equaled the height, at a half of the length. Such a proportion was never maintained when the ships were not very tall but prominent in length.

From the viewpoint of cabins, ancient ships in India were categorized as *Sarbamandirā*, *Madhyamandirā*, and *Agramandirā*. For the *Sarbamandirā*, the cabin was extended from one end of the vessel to the other, and it was used for the transportation of royal treasure, horses, and women. The cabin was located at the middle for the *Madhyamandirā*, which plied mainly during the rainy season, and the *Agramandirā*, which had the cabin at the prow, was used in naval warfare.

One of the major innovations in nautical technology was harnessing wind power by using masts and sails, where ancient shipbuilders in India also excelled. An early fifteenth-century European travelogue thus narrates that the natives of India “build some ships larger than ours, capable of containing 2,000 butts, and with five sails and as many masts” (Conti, p. 27). India’s ancient knowledge on masts and sails is preserved in cave paintings (Fig. 1) and temple sculptures (Figs. 2 and 3). Figure 1, a painting at the Ajanta Caves (525–650 CE), shows that there are three upright masts, each surmounted by a truck, carrying a lugsail (a square sail bent upon a yard that hangs obliquely to the mast). There is also an out-flying jib (a sail borne in front of the foremast) in the ship, which is also square in form. These lugsails and jibs resemble those in the nineteenth-century wooden ships of Europe. Figure 2 (a temple sculpture in Java in the early Christian era) shows a ship with two masts, one long sail, one short sail, and a jib, while in Fig. 3 (a similar sculpture), there are two masts with two individual square sails and also one staysail (jib). Bengal shipbuilders presumably constructed these types of ships since the culture of Bengal was reflected in Java’s contemporary temples.

Raw Materials of the Industry

The quality of a ship is reckoned by its stability, capacity, strength, and speed, which, in the age of wooden ships, were determined by the dexterity of workmanship, as well as the quality of woods that the shipwrights employed. Ancient shipbuilders in India acquired immense knowledge and expertise in this field. Similar to the caste division in the Indian society, they divided woods into four categories: *Brahmana* (light and soft), *Kshatriya* (light and hard), *Vaisya* (soft and heavy), and *Sudra* (hard and heavy). Where woods contained properties of two separate classes, they were categorized as *Dvijati* (mixed). For shipbuilding, however, the *Kshatriya* category of woods was considered most suitable since such ships could withstand any hazards of a turbulent sea for its hardness and also could ply fast for its lightness. For sundry purposes, the *Brahmana* was used as it could be easily joined to any other wood.

To the *Kshatriya* category belonged teak, *gāmbhāri*, *tamāl*, *peal*, and *jackwood*, which were extensively used in Bengal's ancient shipbuilding. There were several references of another kind of wood in the medieval literature, called *manapaban*, which ensured utmost speed to a ship. The use of teak, however, survived down to the early modern age when shipbuilding was resurrected under British entrepreneurship. Owing to its centuries' long use, the teak forest in and around this region was possibly exhausted by the early nineteenth century, necessitating that teak be imported from the neighboring country, Rangoon. Along with teak, however, Bengal shipbuilders employed *sal* and *sisoo* in the early modern age. The former resembled oak in quality but was much heavier and stronger. It grew about 90 ft to the branches and is proportionately thick. The latter grew in various shapes, enabling a builder to make use of it for many purposes. These two species of trees, however, grew abundantly in the northern fringe of the province stretching over the Himalayan foothills and also along its border with Bihar. The later shipbuilders generally used the *sisoo* timber for ribs, knees, and breast hooks (i.e., for the frame of a ship), the

sal for beams and inside planks, and the teak for bottoms, sides, decks, masts, keels, and sternposts.

Cordages that were extensively used in shipbuilding were made of coir (the husk of coconut), ejoo (a fiber obtained from the leaves of sago palm tree), plantain, and sunn. The coir was famous for its elasticity and lightness, the ejoo for its durability, and the plantain for its strength. The Bengal sunn, similar to the quality of Russian hemp, was also used extensively for rope making. The province abounded with all these raw materials. Pine tar (for use in ropes), as well as *dammer* (which was an Indian substitute for pitch), was also locally available in plenty. For sails, local shipbuilders preferred jute cloths (*gun*) from the ancient ages, which artisans spun and wove at their cottages.

Insofar as the need for joining was concerned, the ancient shipbuilders avoided the use of iron nails since the ship might be caught into the influence of the magnetic effect in a deep sea and thus suffer wreckage. They fitted the bottom planks together or mortised them with other materials. Metals, such as gold, silver, copper, and any compound of these, were used only for decoration. However, when the industry was revived in the late eighteenth century, the British entrepreneurs extensively used various metals, including iron, and for these purposes, they imported bar iron, sheet copper, copper bolts, and lead from Great Britain. Locally available iron, brought from nearby districts like Balasore, Midnapore, and Burdwan, was also used to an extent.

Lastly, paints and paint oil were also locally available. The painters mainly used *hurtal* (yellow arsenic), which abounded in Bengal, to get the yellow color. They obtained the blues from indigo and the blacks from rattan charcoal. Hurtal and indigo were mixed together to obtain the greens and the red earth and the ochers for the reds. Ancient shipbuilders generally used white for four-mast ships and red for three-mast ones, while yellow and blue were reserved for two- and one-mast vessels, respectively. Other colors were meant for painting fanciful shapes or forms on the prows. For use in these paints, however, the oil

was obtained from wood oil trees that grew abundantly in the district of Chittagong. In colonial days, this oil was used for coarse works and the European linseed oil was preferred for finer paints.

Method of Construction

Modern shipbuilding is contingent on naval architecture, where every part of a ship is detailed out. Workmen were concerned only with construction based on those designs. That was not, however, the Indian tradition. Without any such blueprints, Bengal shipwrights built vessels relying only on the dexterity and skill of the workers. According to the medieval Bengali literature, there were 12 principal components of a ship: (i) keel (*dārā*), (ii) bottom (*tālā*), (iii) prow (*māthākāsthā*), (iv) deck (*pātātan*), (v) shed (*chhaighar*), (vi) mast (*mālumkāsthā*), (vii) sail (*pal*), (viii) helm (*patwāl*), (ix) chord (*fāns*), (x) oar (*dandakerwāl*), (xi) bamboo pole (*bangsakerwāl*), and (xii) anchor (*nangar*). At the beginning, the keel, bottom, and prow were constructed, keeping in view the dimension of the ship to be built.

Shipbuilding started with a ritual, called *dārābindhā*, where the owner of the ship thrusts a gold nail (*sonārjal*) to the keel with a silver hammer (*hātur*). A similar practice was also performed in Bombay (even in the late 1830s), where a silver nail was thrust. After the ceremony, the keel was placed carefully on the construction site, and the bottom planks were joined to it with nails. The planks forming the bottom of the ship were fayed (or joined) together in a way where caulking was minimum. Indian shipwrights usually rabbeted the planks into each other, filled cottons in the interstices, and applied *dammer* on its entire exterior. When the planks were so joined, “the bottom presents, as it were, one impenetrable surface” (Charnock, v. 3, p. 303). Also, the lower part of the ship was constructed with double or triple planks (with the lighter ones at upper layers) so that they could withstand the force of the tempests to

which they were exposed. It also augmented their natural durability. In fact, the use of an additional plank over a decaying one (i.e., the sheathing) was a traditional practice in India. An eighteenth-century British naval architect observes that these Indian practices of faying and sheathing predate the corresponding knowledge of nautical technology in Europe (Charnock, v. 3, p. 303). Two more facets of Bengal technology should be noted. Firstly, Bengal artisans often built ships in compartments so that a ship could accomplish the voyage even if one of its several parts was wrecked. This is corroborated in a fifteenth-century European travelogue (Conti, p. 27). Secondly, Figs. 2 and 3 suggest that Bengal shipbuilders fitted many curved ribs on the hold. Since those ships were top heavy, outriggers were meant for safety. Once, however, these were accomplished, the prow (*galui*) was fixed, and the hold of the ship was complete.

Then, the deck (*pātātan*) was constructed by joining the planks to the keel. These joinings also obeyed the aforesaid principles. On the deck were fitted the masts (*mālumkāsthā*), yards (*jokābāri*), and helm (*patwāl*) and also the shed (*chhaighar*) and cabin (*raighar*). Finally, it was painted and decorated. Special attention was paid for decorating the prow. Often was it given the shape of a bird like a peacock, a lion, a tiger, an elephant, a buffalo, or a serpent, with their eyes bedecked with jewels.

The quality of raw materials and workmanship in Bengal gave its shipbuilding industry a sharp competitive edge in the international market. A shipping register for 1781–1839 suggests that the average expected life of a Bengal ship was more than 20 years, as against only 11 years for Bristol- or Liverpool-built ships, and 12 years for vessels built on the Thames. After comparing a London-built ship, the *Enterprise*, and a Bengal-built one, the *Forbes*, a contemporary document notes, “Surely this speaks something for the superiority of substantial teak-built vessels, over the oak and fir ships of colder climates” (quoted in Ray, 2011, p.188).

Shipbuilding in India: Wadia Shipbuilders

Rajesh Kochhar
Panjab University Mathematics Department,
Chandigarh, India

The British created a vast overseas empire through their supremacy over the high seas. In their colonial enterprise, they were ably assisted by the Wadia shipbuilders of Bombay (old spellings are advisedly used) who, drawing on their own skills, local tradition, and the raw material available, provided the British navy and merchants with excellent ships.

In the year 1498, Portuguese arrival in India by an all-sea route introduced the navy as a factor in the geopolitics of India, placing the landed rulers

at a disadvantage for all times to come. The Portuguese and the Dutch success brought the British to the Indian west coast in 1608; after 4 years, they inflicted a crushing defeat to the Portuguese at sea. The Portuguese were fanatically anti-Muslim and particularly severe on the Haj pilgrims. The victory of the religiously neutral British was viewed with relief by the Mughal emperors who in turn granted them attractive trade concessions. It was the desire to get such concessions enforced at lower levels that fuelled the (British) East India Company's territorial ambitions. Ironically, the British task was made easier by the Portuguese themselves.

The island of Bombay, which the Portuguese had taken over in 1534, was ceded and granted to the crown of England in full sovereignty under a marriage treaty signed in 1662. Never before had the dowry of a princess been so detrimental to the interests of a kingdom. Bombay was an excellent natural harbor. More importantly, unlike Surat where the British had been permitted to set up their headquarters, it laid outside the territorial reach of the Mughals. The Portuguese viceroy of Goa, Antonio de Mello e Castro, had boldly declared: "I foresee that India will be lost the same day on which the English Nation is settled in Bombay" (Da Cunha, 1900; cited in Wadia, 1957, p. 9). These words turned out to be prophetic indeed.

The instructions from London were "to keep Bombay always the seat of our power and the centre of our trade in India." It gradually became an attractive destination for the native settlers especially the Indian Zoroastrians, the Parsis, who particularly valued the religious freedom and the business opportunities the new city offered.

Until this time, the British had been getting their ships repaired and built mostly in Surat. Like many coastal places, Bombay already had facilities for building small vessels, "but no proper establishment with a dockyard, attendant builder and ancillary factories for rope-making, coopering, etc., existed" (Wadia, 1957, p. 119). What lent urgency to the establishment of a proper shipbuilding facility at Bombay was

the harassment from 1707 of foreign ships by a fleet led by Kanhoji Angre (anglicized to Connajee Angria and variously spelled) and his successors till their defeat by the British in 1751.

The first priority for Bombay was to build coastal boats. The man of the hour was Lowjee Nusserwanjee (ca. 1700–1774) who had been working for a Parsi shipbuilder in Surat since his boyhood and was known to the Bombay officials as the foreman responsible for actually building the ship “Queen.” In March 1736, he, along with ten other carpenters, came to Bombay expressly to build a grab [a usually two-masted, square-rigged coastal vessel]. When the Master Builder, Mr. Robert Baldry, died in 1740, no replacement was sought from Britain. Instead Lowjee was given the charge. From 1740 till 1764, he was generally designated Master Carpenter and subsequently Master Builder.

It was under his guidance that the first dry dock was built in 1750, and others were added later. A subsidiary dock, the Mazagon, was built in 1774. There was also a small private dock, Old Mughal dock, built around 1835, which was rented out to the Peninsular and Oriental Company in 1854 for their new mail service between Bombay and Suez. Remarkably the government post of Master Builder remained in the family for six generations till 1884, when the dockyard was transferred from the Bombay government to the Indian. There were other Wadias working in junior dockyard positions where they continued until 1913. The Wadia skills were made use of by foreign governments, companies, and merchants. The family name Wadia, meaning boatbuilder in Gujarati, was not used in official records, even though later Master Builders sometimes signed their names as Lowjee. All official correspondence was however addressed to the formal name consisting of the given name followed by the father’s.

In the first phase of shipbuilding in Bombay, the emphasis had been on repairs and construction of coastal boats for protection. Things soon changed. Increased merchant activity and marine rivalry in Europe resulted in large-scale felling of oak trees in Britain. In 1772 the Company was prohibited from building any large ships. It

therefore shifted the shipbuilding activity to India. In any case, teak was a better material than oak.

The dockyard was at its zenith during Jamsetjee’s tenure (1792–1821), while his son and successor Nowrojee (1821–1844) “was the last person to enjoy all the rights and privileges attached to the office. After his retirement there was an all round decline in ship building in Bombay” (Wadia, 1957, p. 296). The golden age of shipbuilding in Bombay however spelled disaster for the teak forests in India. The forests in Gujarat and Konkan were soon exhausted and the Malabar forests severely depleted. It is only when iron and steel ships came into increased use that in 1847 a conservator of forests, Dr. Alexander Gibson, was appointed in Bombay.

Racism

Although the Wadias were well regarded in official circles, they did come across racism. In a particularly unsavory incident, in 1781, a dockyard carpenter was flogged in a visiting British navy ship on suspicion of petty theft. When the Master Builder Bomanjee Lowjee himself went to the ship to remonstrate, he was also struck. He immediately wrote to the government stating, “unless they could be supported in their station with reputation they must with reluctance request permission to quit the place and the employment they held under the Company.” When the ship commander stood his ground, it was left to the admiral to write “a healing letter” (Wadia, 1957, p. 164).

The next Master Builder’s revenge against racism was subtler. The frigate *Marquis Cornwallis* built by him in 1800 for the Company was found to be so beautifully constructed and of such great strength that the Admiralty purchased it 4 years later. On the keelson [the timber immediately above the keel], he secretly carved the words: “this ship was built by a d...d Black Fellow AD 1800.” Jamsetjee himself drew attention to this when the ship, since renamed *Ackbar*, returned to the Bombay docks many years later (Wadia, 1957, p. 191).

In 1810, the Wadias built a 74-gun vessel “Minden” for the British navy, their first ship of the line built outside the UK. At the same time in competition to Bombay, a similar vessel was built at Kidderpore on subscription by Calcutta inhabitants and presented to the British navy, which however was not impressed. The Minden saw service during the British-American War of 1812. Francis Scott Key wrote the lyrics of the US national anthem in 1814 aboard the “Minden” where he was detained.

Steam Navigation

Once James Watt’s steam engine became available, it was used for propelling ships. The lead came from the USA, which had no roads or canals, but had large tree-lined rivers that would not mind inefficient engines. The first practically successful steam vessel on a river was launched in 1807 and on the sea the next year. Britain soon caught up, with the British navy acquiring its first steamer in 1819. Incidentally, the first steam-propelled vessel in India was fitted with an engine and built to the plan brought from England in 1819. It was built for Nawab Ghazi-ud-din of Oudh at Lucknow for use as a toy.

The Calcutta merchants were keen to introduce steam navigation on three routes: on the placid north Indian rivers, in the opium and tea trade with China, and between Calcutta and England via the old Cape of Good Hope route. Early steam machinery was rather daunting. It used coal voraciously and was extremely complex for easy maintenance. The merchants neither had the capital nor the patience to experiment. The Company, divested of its trade monopoly in 1813, had no intention of sinking its money into steam for trade, but it had wars to win. The initiative by private individuals looks significant in retrospect but was economically unviable in its time. What gave steam navigation the initial boost was the amphibian Burmese war of 1824–1826. An 8 HP engine privately brought to Calcutta in 1817 or 1818 was used to power a paddleboat that carried troops over creeks and estuaries of the Arakan coast. Similarly, in 1825, the Company bought a private river steamer “Diana” built 2 years

previously to operate against the monsoon winds. It was dubbed “fire devil” by the hapless Burmese (Bernstein, 1960, p. 30).

Bombay’s interest in steam was even more pronounced than that of Calcutta and Madras. Monsoon winds made it easier for a sailing ship to reach Calcutta than Bombay. Steam would give Bombay the benefit of its shorter distance to Europe. After waiting for 6 years for the court of directors to respond to “a distinct official proposition” first made in 1823, the Bombay government decided to go ahead on its own and got the Wadias to build a steamer, cleverly named “Hugh Lindsay” after the skeptical Company chairman. It was a small ship of 411 t with two 80 HP engines, launched in 1829. In the next 4 years, it made a total of five voyages to Suez, all heavily subsidized. Average receipts from passengers and letters stood at Rs.14,225 as against the expenditure of Rs.46,250. The acclaimed success of “Hugh Lindsay” in contrast to the declared failure of “Enterprise” in its voyage to Calcutta via the Cape established the viability of the overland route (Khan, 1971). This had far-reaching and widespread consequences. Bombay became a gateway to India. The Red Sea and the Persian Gulf were scientifically surveyed and the Suez Canal was dug. More importantly all the countries en route lost their independence.

Introduction of steam navigation did not mean the immediate end of sailing ships. The commercial viability of steam came only when engines were greatly improved and ships were made of iron and then of steel. This effectively brought teak ship building at Bombay to a close, bringing to an end a fascinating chapter in colonial history.

From 1736 to 1884, the Wadias built a total of 334 vessels for a wide variety of owners: the East India Company, private merchants, the Nizam of Hyderabad, the Imam of Muscat, and the British navy. Out of these 334, thirty-nine were either specifically built for or subsequently acquired by the British navy during 1777–1849. (For completeness, it may be added that from 1885 to 1936, another 46 vessels were built at the Bombay dockyards.) If we were looking for a single ship to sum up the career of the Wadia shipbuilders, it would have to be the frigate “Trincomalee” built in 1817

and probably the oldest ship still afloat. It served the British Navy for 76 years and was then sold off. It was renamed “Foudroyant” about 1902 and used for the training of boys in seamanship. The original name was restored in 1993 and after that the ship itself. It is now open to visitors at the Hartlepool Historic Quay.

The Wadias received three land grants in Bombay, in 1783, 1821, and 1849 (in two installments) and in 1884 on the retirement of the last Master Builder. In addition, there were a number of presents of medals, rulers, and shawls. The prestige carried by the shipbuilding Wadias helped other members of the clan in establishing themselves in various lines of business.

From Ships to Industry

The introduction of steam necessitated the upgrade of Wadia skills. Master Builder Nowrojee Jamsetjee (1774–1860) sent his son Jehangeer Nowrojee and nephew, Hirjibhoy Merwanjee, for an extended stay during 1838–1841 in England, where they studied naval architecture at the Royal Dockyard at Chatham under the Master Shipwright. Jehangeer rose to become the Master Builder himself.

Historically, far more significant was the 15-month England sojourn during 1839–1841 of Ardaseer Cursetjee (1808–1877) then an Assistant Builder at the dockyard and son of Cursetjee Rustomjee who later (1844–1857) became the Master Builder. “The prompt repair of the engines of the numerous steamers” arriving in Bombay posed a problem. “Few of the European engineers and drivers could withstand the climate, and those who were enabled to do so proved so troublesome that a remedy for the inconvenience appeared of paramount importance” Cursetjee, 1840, v). The remedy was Ardaseer’s officially sanctioned and partly financed visit. While in England, he spent his time getting practical experience in construction and maintenance of steam engines and moving in influential circles. He successfully applied for the post of Chief Engineer and Inspector of Machinery at the Company’s factory and foundry in

Bombay. The Bombay newspapers variously commented that there would be a “body of English workmen” under his charge.

This appointment in turn helped him to become the first Indian to be elected as a Fellow of the Royal Society of London in 1841. The distinction seems to have had no impact whatsoever in India. Bombay was perhaps too practical to make sense of an honor bestowed in London, while it was too early for Calcutta to be interested. In any case the Royal Society then was more of a gentleman’s club than the learned body it became later. Ardaseer was in effect introduced to India 100 years later, in 1944, by the visiting Secretary of the Royal Society. Belatedly, in 1969, an Indian stamp was issued commemorating Ardaseer Cursetjee (Kochhar, 1993).

The Wadia’s familiarity with the steam engine had far-reaching consequences. It led to the mechanization of the textile industry. Ardaseer Cursetjee’s son Nusserwanjee, who had joined the dockyard in 1844 at the age of 12, quit his job 6 years later as he was directed to Manchester by the well-known Parsi textile magnate and philanthropist Sir Dinshaw Petit to select machinery and engines for Petit’s textile mill. Nusserwanjee in turn sent his son Nowrosjee “to school in Liverpool and for factory training.” In 1879 Nowrosjee Wadia set up the Bombay Dyeing and Manufacturing Company, which has maintained an uninterrupted record of dividend payment since 1885. Nowrosjee established another successful mill, the “Century Mills,” which however was sold by his other heir (Koffend, 1979, pp. 37–41). The Bombay Dyeing’s former Chairman Mr. Neville Ness Wadia, in 1994, did not seem to know much about his FRS ancestor, certainly not that he had published a diary from England. He was greatly helpful in providing source material on the Wadias to this writer.

Shizuki Tadao

Nakayama Shigeru

Shizuki Tadao was a Japanese natural philosopher, born in 1760. He was adopted by the Shizuki family, whose head was a government interpreter from the Dutch. In 1776 he became an assistant interpreter, succeeding his adoptive father, but he retired from that post the following year because of ill health. After leaving public service, he spent the rest of his life in the private study of Dutch books and in contemplation. He died in 1806.

He wrote books about the Dutch language and partially translated the Dutch translation of Engelbert Kaempher's *Geschichte und Beschreibung von Japan* (History and Description of Japan). But Tadao's major work was *Rekisho shinsho* (Introduction to True Physics), a compilation of his own theories on natural

philosophy, inspired by his translation of the Dutch version of John Keill's *Introductio ad veram physicam* and the *Introductio ad veram astronomiam*.

In advocating Newtonianism, Keill's work had a polemical tone, and more importantly and quite unlike the readjusted interpretations of later authors, it dealt in abstractions and included a great many elements of natural philosophy. The book especially suited Tadao's inclination toward natural philosophy and Tadao thus became the first Newtonian in the East. He established unitary *qi* (energy) and its dual function (rarefaction and condensation) as the basis for his natural philosophy. He was not successful, however, in relating the natural philosophy that he derived from the theory of monistic *qi* to Newtonian dynamics.

Tadao also raised the question of why the planets rotate and revolve in the same direction in planes not greatly inclined to the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). He proposed a hypothesis concerning the formation of the planetary system, which resembles the celebrated hypothesis of Kant and Laplace.

Shushu Jiuzhang

Ulrich Libbrecht

The *Shushu Jiuzhang* (A Mathematical Book in Nine Chapters) is a Chinese mathematical work, written by ► [Qin Jiushao](#) and published in 1247. This book is one of the highlights of Chinese mathematics of the Song-Yuan period, 960–1368.

The work is not organized according to mathematical methods, but topically arranged according to domains of administrative practice, with the exception of Chap. 1. The nine chapters are as follows:

1. Indeterminate analysis (*Dayan*);
2. Heavenly phenomena, which dealt with chronological and meteorological questions;
3. “Boundaries of fields,” which covered surveying;
4. “Telemetry” or measuring at a distance, a kind of prototrigonometry;
5. Taxes and levies of service;
6. “Money and grain,” i.e., taxes;
7. Fortifications and buildings;
8. Military affairs; and
9. Commercial affairs.

An investigation of the socioeconomic information contained in the work proved that all the information was indeed related to the Southern Sung society, especially regarding money and currency (including paper money), credit systems, commercial life, harmonious purchase (*heti*), transportation problems, construction of dikes, taxes and levies of service (*fuyi*), architecture, military affairs, and astronomy. This could mean that the work was written for practical purposes, although it was, partly because of the Mongol invasion of China, never used as a handbook for practical training.

The basis for the common arithmetical procedures was the ancient mathematical classic, the *Jiuzhang Suanshu*. There was one method, the *dayan* rule, which Qin Jiushao learned when he worked in the Board of Astronomy. This method is preserved only in Qin’s work.

As for notation and terminology, it is important to note that the zero was printed for the first time in this book, so that we have a complete decimal place-value system. The arithmetical algorithms are the traditional ones, as are the geometrical methods and trigonometrical procedures. The most important part of the work is the “algebra.” This dealt with simultaneous linear equations, determinants, and series and progressions. Also covered were numerical equations of

higher degree, an extension of the method for square and cube root extraction used in the *Jiuzhang Suanshu* and the *Ten Books of Mathematical Classics*. This method is the same as the Horner-Ruffini procedure. The most important part is undoubtedly the Chinese Remainder Theorem, solved by means of the *dayan* rule. It is the solution of the problem:

$$N = r_1(\text{mod}_1) = r_2(\text{mod}_2) = \cdots = r_n(\text{mod } m_n)$$

It is remarkable that Qin Jiushao was able to solve problems where the moduli are not relatively prime – a method not known to Euler and Gauss, and only solved definitively by Stieltjes in 1890.

Silk and the Loom

Dieter Kuhn

In China the raw material silk dominated textile technology as a whole, and dictated the development of looms and their technology in particular. Thus the weaving methods and the patterns depended to some extent on the loom technology available.

The biological prerequisites for silk production on a commercially significant scale are domesticated silkworms *Bombyx mori* L. (sericaria) [*jiacan*] which belong to the family Bombycidae in the order of the Lepidoptera

nocturno and various mulberry trees of the family of the Moraceae, such as the *Morus alba* Linn. (*baisang*), *Morus bombycis* Koidz. (*jingsang*), and *Morus alba* var. *multicaulis* (*lusang*), commonly called the domestic mulberry (*jiasang*). Silkworms are generally fed with the fresh leaves of the mulberry tree.

Not only were these two prerequisites present from an early stage in China, as can be seen from pictographs on bone inscriptions of the Shang era, but their biological connection was also recognized. Various archeological discoveries, fragments of textile, and imprints show that in many areas of Neolithic China a form of silk technology already existed which clearly belonged to a long and practically, perhaps even experimentally, oriented agricultural tradition. The production and treatment of silk had begun many years before and by then had already reached a high technical level. So far the earliest find of silk in China is dated between 2850 and 2650 BCE. The earliest cocoons of the domesticated spinner are from the Tang dynasty (618–907).

To understand the importance of silk as far as weaving and the development of weaving patterns are concerned, it is essential to look at the genuine properties of a single silk thread. Unlike other textile fibers silk is not spun but reeled. Silk-reeling (*sao si*) involves taking up the ends of fibers from several cocoons and combining them into a thread. It takes place just before the moth tries to break through the cocoon. This timing is crucial if endless silk threads are required. The length of the cocoon-filaments which can be obtained varies between 700 and 900 m, but without a silk-winding instrument, a reel, and a water basin in which to float the cocoons, silk-reeling cannot be performed. Through the centuries hand-driven silk-reeling was practiced as a seasonal business in small-scale family production. From the terminology used it is certain that prototypes of silk reels and silk-reeling frames (*saochechuang*) were known in the Zhou period. The earliest detailed description of the treadle-operated, highly mechanized silk-reeling frame is from ca. 1090.

Loom weaving, the production of even-textured fabric, requires that the warp threads be kept at a consistently high level of tension. The warp threads (*jing*) are those which, in parallel, run lengthwise across the loom; the weft threads (*wei*) are introduced laterally at right angles to them. A high weaving tension necessitates the use of comparatively elastic warp threads of a kind not naturally found in raw silk. This elasticity is obtained through winding or throwing or else doubling and twisting the thread. Various spinning techniques could spin the thread in the requisite manner. In China the spindle wheel (*fangche*) had been in use since the middle of the first millennium BCE. The spindle wheel was not only very efficient in the spooling of threads, which means transferring a thread from a reel to a spindle, but also most useful in the processes of doubling and quilling, when an empty spindle is filled with a twisted thread which now combines two or three threads in one. Much has been published about the origin of the spindle wheel in the East and in India, but all the pictorial and textual evidence available points to China as the geographical area where the spindle wheel originated in the context of silk technology, especially the spooling and doubling process, as pictured on some Han stone reliefs. It took a long time before the spindle wheel made its appearance in Europe in the thirteenth century. All these inventions and innovations in the processing of silk threads have to be seen in the context of the treadle-operated loom (*jiaotaji*) which was equipped with two treadles in order to mechanize the opening (*kaikou*) of the shed. Thus a clear shed for the shuttle (*suokou*) was formed through which the weft thread could be passed. Such a loom was employed to weave simple tabby fabrics to standards on a large scale. From its structure it may be described as a combined horizontal-vertical or oblique warp sheet loom (*xiezhiji*). Depictions of the loom on stone reliefs from Han times which were found in Shandong, Jiangsu, and Sichuan provide ample evidence of this type of loom. A more complicated loom with a treadle mechanism for the forming of the shed and a system of draw cords (*tihuaxian*) or pattern rods (*wen 'gan*) which

looped the warp threads required for the pattern already existed in Zhou times.

If maximum benefit was to be got from the exceptional length of the silk threads, then it was only logical to dress the loom with a silk warp. For this one needed a warp beam (*jingzhou*). The width of the fabric was determined by the length of the warp beam, and by the ideal working width for the weaver, who not only inserted the shuttle containing the weft, but also operated the treadles with her feet so as to form the sheds. In addition, she would have to perform other operations in order to create the particular pattern. On account of these factors, most fabrics of the Han era as well as later generally had a width of about 50 cm (two *chi* and two *cun*). The length varied between 9 and 12 m. The qualities of silk as an ideal warp thread and hence too the dominance of the warp in the weave resulted in the weave pattern being created by accentuating the warp threads. From the Zhou era (1045–221 BCE) until the early Tang era (618–907), therefore, Chinese silk possesses a warp pattern unlike that of other cultures, which, due to differences in the raw material, was produced on wholly different looms and which is weft patterned. Only in Tang times did the patterning technique change to the weft, which resulted in more colorful fabrics. Although it is known from a few silk fragments that the weft pattern was practiced in early China, the change in weaving technique in Tang times was certainly due to influence from the region of Samarkand or Persia.

Several types of looms were already in use and operated as early as Han times (206 BCE–AD 220). They are documented in historical works from Han and Jin times, and especially in the agricultural and encyclopedic works from the Song, Yuan, Ming, and Qing dynasties (960–1911).

The loom which combined 70 or even more movable shafts (healds) with the function of many treadles (*duozong duonie*) was widespread. Although this type of loom was difficult to set up, it was operated until recently in Sichuan province. The big advantage of this type of loom was that one weaver could operate it easily and quickly. Furthermore its advanced and highly

efficient patterning equipment qualified it for the production of so-called brocades and other complicated weaves.

Another type of loom which is not clearly distinguished in the Chinese publications from the above-mentioned loom made use of figuring healds or pattern rods (*tihuazong*, *wen 'gan*), which were manually lifted. Textual sources mention up to 120 patterning devices. This ingenious hand-operated patterning device was already used on the backstrap loom (*yaoji*) in very early times. The simple backstrap loom originally had no wooden frame but consisted exclusively of functional parts. The weaver sat on the ground. In many old publications it is depicted with a wooden framework. It was used until recently. The earliest weaving implements which may be ascribed to such a loom were excavated from the site of Hemudu, datable to ca. 4300 BCE. It may be justified to assume that the patterning technique with pattern rods which can be created in a sitting position on the ground is older than the use of looms with shafts and treadles which require a wooden frame. Although the simple type of backstrap loom was an excellent device for weaving on a comparatively small scale, it had its obvious limitations which were set by the length and width of the circular warp. In the view of Chinese textile historians this loom with pattern rods belongs to a loom category either of an early primitive type or of ethnic minorities. Only after the horizontal backstrap loom had been equipped with a real warp beam, supported by a wooden framework, which helped to facilitate its operation, can it be regarded as a loom which worked economically and which was suitable for silk weaving with patterning on a large scale. In all probability and in the opinion of a few eminent Western weaving specialists, such a loom with two shafts producing a tabby ground and a system of pattern rods of the heddle rod type that were lifted by the weaver as required by the pattern was the type of loom used and preferred to all others for the production of complex-patterned weaves before Tang times in China.

The third type of loom before Han times was a forerunner of the Chinese drawloom. It employed

a string heddle patterning device (*shuzong tihua zhuangzhi*) and a simple treadle-operated shedding device. During Eastern Han times its equipment was improved in such a way that the whole “machine” (*ji*) gained the structural and functional features of a real drawloom (*hualou tihuai*). This drawloom was equipped with a figure or harness tower and all the lifting devices for the warp threads required. Furthermore there were lifting and depressing shafts. It was operated by a weaver and a drawgirl. This type of loom, which was fashioned in a large variety, dominated the production of high-quality polychrome-patterned silk fabrics until the late nineteenth century when Western looms were introduced into China. Some Western historians of weaving technology have ruled out the use of a drawloom in Han times in China and suggested that it was invented somewhere in the region of Samarkand, Persia, or even the Near East. To support their notion they practically demonstrated that even difficult polychrome weaves could have been produced on pattern rod looms. However the “Rhapsody on Women Weavers” bears witness to the fact that the drawloom with all its characteristic features was already in use in the big workshops of China as early as the first half of the second century AD. The earliest technical description and illustrations on the subject were published in the *Ziren yizhi* (Traditions of the Joiners’ Craft) of 1264.

Silk in Bengal

Indrajit Ray

Department of Commerce, University of North Bengal (on lien), Darjeeling, West Bengal, India
Cooch Behar Panchanan Barma University,
Cooch Behar, West Bengal, India

Silk manufacturing is an important facet of industrial heritage in Bengal. The high profile of this industry is confirmed in many European travelogues during the late medieval and the early modern periods. They narrated how the province fed different markets in the Indian continent – and even beyond – with decorative pieces of silk cloth. Village establishments, such as Cassembazar, might have turned out more than two million bales of silk a year. Working on low technology and capital, village artisans in Bengal designed their own implements and organized production at their huts. They left the distant sales of their fancy outputs to the trading communities like the Marwaris and the Parsis, who created their markets at Surat, Delhi, Lahore, and Agra. Later on, they were sold to the Portuguese, the Dutch, and the English, who sold them at European outlets. In 1703–1708, the English East India Company annually exported about 162,000 lbs of raw silk and 28,000 pieces of silk fabrics from Bengal. To these we add the export of the Dutch East India Company as also

enormous intakes in India's domestic markets to get an idea about silk-related economic activities in Bengal.

There are three distinct branches in silk manufacturing: (a) sericulture (cocoon rearing), (b) raw silk (cocoon spinning), and (c) weaving. Actually, the Italian (Novi) technology put a dent in indigenous practices during the British Raj. But that was confined to raw silk alone, leaving cocoon rearing and weaving to the fiefdom of native artisans. Also, as a courtesy to domestic weavers, indigenous technology continued predominantly in raw silk manufacturing.

Cocoon Rearing

Traditionally, Bengal artisans reared four species of cocoon: *bara-palu* (*Bombyx textor*), *chhotapalu* (*Bombyx fortunatus*), *nistari* (*Bombyx craesi*), and *cheena-palu* (*Bombyx sinensis*). The *bara-palu*, yielding by far the best quality of silk, breeds once a year as against as many as eight times by others. They are accordingly called univoltine and multivoltine. Though less productive, the *nistari* was most popular among rearers because of the softness and fineness of the silk they produce. Silkworms were, however, prone to fly attacks, especially when all the possible eight crops were tried for. Artisans, therefore, generally reared cocoons in one *bund* (i.e., one season) and nourished the mulberry trees in the next, yielding only four crops in a year. Generally, they opted for three with the *nistari* and one with the *chhotapalu* or the *bara-palu*.

The art of cocoon rearing revolved around the selection of seed cocoons and their feeding. In search for good seeds, rearers often walked for several miles – sometimes 50–60 miles at a stretch – and stayed at *joars* (silk-rearing centers) for days to judge the quality of seeds that depended on their ripening process. This was, indeed, an expert job. Expertise was also involved in feeding, especially in respect to quantity and quality of food, as well as time scheduling. Their singular diet, the mulberry leaf, contained water, fiber, color, saccharine, and resin. Of these, saccharine accelerated their

physical growth, and resin ensured the secretion of silk in proportion to their sizes. Rearers, therefore, avoided fermented or worn-out leaves that were deficient in these substances.

More frequently, rearing took place in mud-built houses of roughly 24 × 15 f. in area and 9 ft in height, where about 256,000 worms could be stored at a time. Such a hut accommodated five big bamboo mats (*ghurrahs*), each having a capacity to contain 15 *dalis* (trays), made of bamboo. Rearers thinly spread seed cocoons over those *dalis*, and, in 8–16 days, moths came out. Immediately, they paired together and remained so for several hours. When they were separated, the males were thrown out so that the females could lay eggs uninterruptedly. The multivoltine moths, however, laid eggs on the same *dalis*, which hatched in 8–16 days. For the univoltine moths, a piece of rag was spread on each *dali*. When eggs were laid, those were preserved in an earthen vessel. It took about 11 months for them to hatch.

Tender mulberry leaves, finely chopped, were the appropriate diet for newborn worms. For the initial 3–4 h, they ate vigorously but spoiled the *dalis* with excrement. For the sake of cleanliness – which was imperative for their survival – rearers put them on separate *dalis* and sprinkled fresh leaves on them. Food was, however, served four times a day regularly, save the day of molting. There were four molts for silk worms when they refused food. After awakening, they shed their skeins and began to eat again. Since their sizes were enhanced about three times after each molt, a proportionately larger amount of food was required, and that with more mature leaves. After the fourth molt, however, they refused to eat and swung their heads restlessly, spitting out silk fibers. At this stage, rearers placed them on the spinning mat (variously called *chandrakies*, *tâlis*, *chânces*, and *fingás*) (see Fig. 1).

On this mat, cocoons were spun in 2 days during the summer and four in the winter. If any delay was noticed, rearers put the mat in the morning sun and also near a fireplace in the winter night.

Silk in Bengal, Fig. 1 *Chandraki* (spinning mat) (Source: N. G. Mukerji, A Monograph on the Silk Fabrics of Bengal, p. 12)

Cocoon Spinning

Two types of spinning were followed in the indigenous sector: the *khamru* spinning for “healthy” cocoons and the *matka* spinning for “pierced” cocoons, i.e., the cocoons where moths came out.

Khamru Spinning: This was the widely held technology in Bengal, which processed more than half of its cocoon outcrops even in the hey-days of the *Novi* culture. The technology was embedded in an apparatus called *ghai*, which might be operated by one set of artisans or double the set. They were called the single *ghai* and the double *ghai*. A model of the latter, as used in the Rajshahi district of Bengal, is shown in Fig. 2.

The apparatus consisted of four components: (a) two fireplaces at A_1 and A_2 , as in Fig. 2, with basins (called *ghai* or *karai*) on their top; (b) two *banti-kals* at B_1 and B_2 (Fig. 2), each made up of

Silk in Bengal, Fig. 2 The double *ghai*. (a) The *banti-kal*; (b) the *khelná* on *ará*; (c) the *tahabil* (Source: N. G. Mukerji, A Monograph on the Silk Fabrics of Bengal, p. 25)

a block of wood and an arc-shaped iron with a few holes on it (see **a** in Fig. 2); (c) two *khelnás* (or *ghargharis*), each on an *árá* at C_1 and C_2 , as in Fig. 2 (the *árá* was a structure of two wooden posts where the *khelená*, a wooden rod with elongated holes, were attached to a pulley (see **b** in Fig. 2)); and (d) two *tahabils* at D_1 and D_2 . The *tahabil* – a wooden structure as seen in **c** in Fig. 2 – had one iron handle on the left and a wheel on the right. The wheel was connected by a belt with the pulley of the *árá*. Threads were collected at the central part of the *tahabil*. However, if there were two holes in the *banti-kal*, two skeins could be reeled simultaneously from the basin. Through those holes of the *banti-kal*, the skeins were passed on to (c1) and (c2) of the *khelná*. When the iron rod of the *tahabil* was manually rotated, the pulley of the *árá* was also rotated so that skeins were spun into a single thread on the *khelná*. Finally, the threads were collected on the *tahabil*.

Proper processing of cocoons was sine qua non for good spinning. It started with exposing them to the sun, followed by steaming, so that pupas were killed, and the cocoons became soft. Artisans thereafter put them in boiling water and sought their ends with the help of a brush or a bundle of sticks. With those ends in the left hand, they shook cocoons in the water in such a way that a greater length of those cocoons was worked off. For spinning, however, 10–20 ends were taken together to divide them in two lots if

there were two holes on the *banti-kal*. Each of those lots was then pushed manually through the holes of the *banti-kal* and the *khelná*. For the double *ghai* apparatus, there were two winders (*pákdárs*) at *tahabils* and two spinners or reelers (*kátánis*) at basins. As the winders revolved the handle at *tahabil*, cocoons were worked off at basins, where the spinners sat and managed the cocoons to unfold properly. When adequately twisted, those threads were collected at *tahabils*.

Matka Spinning: This was an alternative technology which could spin pierced cocoons where there were several ends. A large quantity of such cocoons usually piled up at the rearers' huts every season. Destitute persons, especially widows in the artisan's family, took up this profession as it involved a very low amount of capital.

This technology required three rudimentary implements: a spindle (variously called *teko*, *tékia*, *tākur*, *jūta*, and *jāmtākur*), a bobbin (*latai*), and an earthen vessel. The spindle was made up of thin bamboo, about 10 in. long, with its upper end acting as a hook to hold fibers. An earthen disc was attached to its lower end and acted as a fly shuttle. The *latai* was a conical bobbin, about 6 in. in length, with a long handle. It was also made of bamboo. The earthen vessel was, however, required to keep up pierced cocoons. These implements are seen in Fig. 3 on *matka* spinning.

The process started with kneading pierced cocoons with mud so that the strands of those

Silk in Bengal,

Fig. 3 *Matka* spinning
(Source: N. G. Mukerji,
A Monograph on the Silk
Fabrics of Bengal, p. 23)

cocoons could be drawn out one by one. The spinner then took out a few strands together and attached them to the spindle. When she revolved the shuttle, those strands were twisted into a single thread. She then collected the thread at the base of the spindle and repeated the process. Generally, 400 cocoons were thus spun in a day. At the end of the day, those threads were taken out of the spindle and reeled on the *latai*.

Silk Weaving

The *khamru* silk was generally used in indigenous weaving. Weavers always preferred to unwind the skeins – for the sake of the uniformity of thickness as also the continuity of thread in each *latai* – and, in some cases, to the twisted (*pakwan*) threads. As a rule, they used *pakwan* threads as warps in superior fabrics and the *kham* (untwisted) threads in inferior fabrics. For wefts, the latter was universally used.

Unwinding (Phiran): Threads were unwound using a bamboo-made wheel (*polti* or *chorki*) and

a *latai* (see Fig. 4). The former had a long stick, which was planted loosely on the ground so that it could revolve. The *phiran* artisan put the skein of silk around it and knotted it with the *latai*. While revolving the *latai* with the left hand, the thread passed through the thumb and the index finger of the right hand so that its thickness could be judged. Since the threads of equal thickness were wound on one *latai*, 3–4 *latais* were sometimes required to unwind one skein.

Throwsting or Twisting: Five appliances were used in traditional throwsting (Fig. 5): (i) a *latai* (see A in Fig. 5), where filaments had been collected after unwinding; (ii) an iron guide (called *loibangri khunti*) (see L in Fig. 5); (iii) a cane-made structure (called *dôl*) with holes on it, as seen in Fig. 5b, fitted on bamboo posts; (iv) a number of *takurs* (see C in Fig. 5), i.e., long pins with mud weights at the bottom; and (v) a number of *thhaks*, i.e., holes in a structure of bamboo that was fitted on two posts (see Fig. 5a). The *thhaks* were placed parallel to the *dôl* at a distance of about 27 yards, and the *latai* and the iron guide were planted nearby the *dôl*. From the *latai*

Silk in Bengal,

Fig. 4 Unwinding of skeins (Source: N. G. Mukerji, A Monograph on the Silk Fabrics of Bengal, p. 36)

Silk in Bengal,

Fig. 5 Twisting of raw silk. (a) The *thhák*; (b) the *dól* (Source: N. G. Mukerji, A Monograph on the Silk Fabrics of Bengal, p. 38)

a number of silk filaments were passed successively through the iron guide, the first space of the *dól*, and the uppermost space of the *thhák*. They were brought back through the second uppermost space of the *thhák*, and the second space of the *dól*, to be finally knotted with a *takur*. The other ends of those filaments were then snapped at the iron guide and knotted with another *takur*. There were thus two *takurs* hanging at two ends of those filaments. Usually, seven sets of filaments were thus arranged with 14 *takurs* in such a way that their ends hung at a same distance from the ground.

The throwster (*pakwan*) successively rubbed the pins of those *takurs* between the palms of his hands so that they simultaneously revolved fast without any interruption. When the *takurs* initially hung 9 in. from the *dól*, the thread was

considered well twisted when it was shortened by 9 in. On this apparatus, a throwster could twist 14×27 or 378 yards at a time.

Weaving: Silk was woven in a traditional loom that was also used in cotton weaving. Fig. 6 displays its basic mechanical principle. A weaver first arranged the warp horizontally on the loom, such as the figure displays with a warp of eight threads. His or her next task was to intersect the weft threads through the warp, which the mechanism of the loom helped him to perform. At A of Fig. 6 there was a roller where woven materials were collected. There were two pairs of laths, each called a *headle*. One of each *headle* was above the warp and the other below it, and they were joined together by four strong threads. There were three loops in each thread, the thin central one being meant for the warp thread to

Silk in Bengal, Fig. 6 Mechanical devices of a loom (Source: L. Hopper, *Silk: its production and manufacture*, p. 68)

pass through (see C in the figure). Through the front *headle* loops, the first, third, fifth, and seventh warp threads passed, and through the back *headle* loops, the second, fourth, sixth, and eighth warp threads passed. The figure, however, shows that upper laths of the *headles* were joined together through a pulley, and their lower laths were attached with treadles.

If one treadle was pressed down, four warp threads were sunk so that the weft thread could be passed through them. When this was followed by pressing the other treadle, the second opening got ready for the return of the weft. This was how the weft was woven through the warp.

Various types of weaving were done using this principle. For satin weaving, for example, eight weft threads were taken together, and one after another, they passed over one warp thread and under seven of its consecutive threads. They were so arranged that there were equal spaces between satin ties, both vertically and laterally.

Sinān ibn Thābit

Yvonne Dold-Samplonius

Abū Saʿīd Sinān ibn Thābit ibn Qurra was born in Baghdad ca. 880. He was the son of the translator and scientist Thābit ibn Qurra (ca. 830–901), who dedicated his *al-Dhakhīra fī ilm al-tibb* (Treasury of Medicine) to him, and the father of the mathematician and astronomer ► [Ibrāhīm ibn Sinān](#) ibn Thābit (908–946). His family came from ḥarrān, crossroads of caravan routes and cultures on the Upper Euphrates, and the religious center of the Sabian sect. One of the most famous physicians of his time, he directed the hospitals and medical administration of Baghdad under the reign of the Abbassid Caliph al-Muqtadir (908–932). He also served as physician to him and to his successors al-Qāhir (932–934) and al-Rāḍī (934–940). Under the former’s persecution of the Sabians Sinān had to convert to Islam. He later fled to Khurāsān, and returned when al-Rāḍī came into power.

Sinān’s work, as catalogued by Ibn al-Qifṭī, can be divided into three categories: historical-political, mathematical, and astronomical; no medical texts are mentioned. None of it is extant. In the first category he wrote a description of the

life at the court of Caliph al-Muʿtaḍid (892–902), his father’s protector, and a sketch for a government along the lines of Plato’s *Republic*. Both treatises are mentioned by al-Maʿsūdī, who criticizes the latter, adding that Sinān should rather have occupied himself with topics within his competence.

Four mathematical treatises are listed, of which two cannot be by Sinān, since the dates given were in the second half of the tenth century. Of the remaining two, one is connected with Archimedes’ *On Triangles*, whereas the other consists of an improvement, with additions, of the book by Aqāṭun (Yāqūt = Euclid), *On Elements of Geometry*.

As to the third category, only the content of the *Kitāb al-Anwāʾ*, dedicated to al-Muʿtaḍid, is somewhat known through excerpts given by ► [al-Bīrūnī](#) in the *al-Āthār al-bāqīya min al-Qurūn al khāliya* (Chronology of Ancient Nations). A *Kitāb al-Anwāʾ* is a kind of almanac describing the astrometeorological properties (*anwāʾ*) of the individual days. Sinān’s almanac is fundamentally based on an anonymous Arabic translation of Ptolemy’s *Phaseis*, in which he provides the times of the rising and setting of prominent fixed stars. Other sources are ► [Ibn Māsawayh](#) (d. 857) and Hippocrates, as well as personal contributions by Sinān. According to al-Bīrūnī, Sinān also relates an Egyptian theory and one by Hipparchus, on where to fix the beginnings of the seasons. Another treatise, seemingly also of astrometeorological content, is on the assignment of the planets to the days of the week, composed for the Sabian Abū Ishāq Ibrāhīm ibn Hilāl (ca. 924–994). The seven planets were important in Sabian religion; each one had its own temple. Ibn al-Qifṭī lists several works on Sabian rites and religion. Sinān died, probably in Baghdad, in 943.

Case 7093, Université Paris 7 - CNRS, Paris,
France

This book (*The Jade Mirror of the Four Unknowns*, also translated as *Precious Mirror of the Four Elements*) by Zhu Shijie 朱世傑, dating from 1303, appears to represent the most advanced achievement of the mathematical tradition of polynomial algebra or the “procedure of the celestial unknown (lit.: origin) 天元術” which developed in North China in the second half of the thirteenth century. Jock Hoe (1977) describes the history of its reception among mathematicians and historians in both ► [East](#) and ► [West](#). The *Siyuan yujian* shares the same basic features with the first book that has come down to us on this topic, Li Ye 李冶’s (or Li Zhi 李治’s, according to the name chosen for this scholar) *Ceyuan haijing* 測軍海鏡 (Sea Mirror of the

Circle Measurements, 1248). The mathematical knowledge it contains is presented in the form of problems, the first four of which lay the foundations for the whole book by gradually presenting, though extremely concisely, how to use polynomials with up to four indeterminates to solve given problems. Mirroring the intimate relationship that the right-angled triangle had with the topic of algebraic equations, and later of polynomials, from the very first appearance of these matters in China, these problems all concern the right-angled triangle, as do 101 of the 284 problems that follow in the *Siyuan yujian*. Once a problem is set, Zhu suggests the choice of one or several unknowns to form polynomials on the basis of the conditions given in the terms of the problem. In the case when one unknown suffices, like Li Ye, Zhu forms two *polynomial expressions*, representing the same quantity, and thus by elimination between them establishes an algebraic equation, a root of which is the unknown sought. Since Zhu does not explain the algorithms, similar to the so-called Ruffini-Horner ones, that can be used to determine this root, he seems to have assumed the reader's knowledge of this procedure. They are found in ► [Qin Jiushao](#) 秦九韶's ► [Shushu jiuzhang](#) 數書九章 (Writings on Mathematics in Nine Chapters, 1247) and seem to be common knowledge in the milieu developing the "procedure of the celestial unknown." Yet Zhu elaborates them further, especially in cases where the result is a rational number; he then systematically introduces techniques to expand the root sought.

These polynomials he uses are written in the form of an array of numbers, as in Fig. 1, where the indeterminate and its successive positive or negative powers receive a positional expression. Note that the writing of a polynomial differs from the writing of an equation, as in Fig. 2, in that the constant term of the polynomial is indicated, being accompanied by a character, thus allowing the polynomial to contain any power of the indeterminate.

When more than one unknown is needed, Zhu designs several equations involving them, which he represents by tables of numbers, where again position is used to express the various powers of

the unknowns. For two unknowns, the vertical direction refers to one unknown whereas the horizontal one refers to the other; the surface of the plane suffices for any monom to be represented by its coefficient written in an appropriate place on the counting board, as in Fig. 3. Yet for three or four unknowns, limitations occur in the representation of all possible monoms and new positions on the counting board are brought into play, but in a less systematic way, as in Fig. 4.

In contrast to equations with one unknown, such equations need the constant term to be indicated by a character. Once these equations are determined, elimination is performed between them until an equation with only one unknown

is obtained, which is then solved. Several techniques are used for this purpose, the most basic one resembling the elimination between linear equations put into play by the algorithm to solve systems of simultaneous linear equations presented in the Han book ► [Jiuzhang suanshu](#) 九章算術 (The Nine Chapters on Mathematical Procedures). The difference lies in the fact that now the terms involved in the procedure of elimination are polynomials, and no longer numbers. Stress must be placed on a conceptual gap. In contrast to the case for one unknown, the only one Li Ye dealt with, the elimination no longer bears on polynomials representing a given *quantity*, but rather on equations with several unknowns representing a *relationship* between the unknowns.

In the rest of the book, this apparatus is applied to all kinds of mathematical situations, such as geometry and summation of series, involving various applications to economic or social life.

Song Ci

Hong Wuli

Song Ci was born in Jianyang in 1186 of the Southern Song Dynasty and died in 1249 in Guangzhou. He was a forensic scientist, an expert in legal medicine.

A native of Jianyang (now Jianyang County, Fujian Province), Song Ci was born to a family of middle-class bureaucrats. His father was Song Huifu. He was well educated and passed the feudal examination at the highest (imperial) level. He held several posts, including the confidential secretary of the local government, county magistrate, and provincial officials until he was promoted to the provincial official responsible for law suits and jail affairs. At that time, most feudal officials did not take their responsibilities seriously, especially those involving the law, resulting in the pile up of unsolved law suits. Many were legal offenders themselves. Song ordered deadlines to sort out all these cases. Eventually, he cleared a backlog of over 200 cases (Gao, 1978).

During his tenure, he set up a whole series of rules for examiners of the wounded or the dead. He stressed that legal medical experts or officials must, under the accompaniment of an examiner, arrive at the spot as soon as possible, and that no fumigation or incense was to be used. The officer or expert should examine the case in person, instead of hearing the examiner's report. He also claimed that "the most important issue in criminality is the death sentence, which should

be carefully understood at the very beginning of the case by serious investigation”. He also pointed out that the malfeasance of prison officials always begins with a tiny error during the investigation. Lack of experience and cursory investigation are the direct causes of wrong cases and unjust verdicts. He criticized or even punished those fraudulent examiners whenever cases were in question, and he pondered carefully and conscientiously so that few wrong conclusions were drawn (Song, 1981). Based on his long-term practical experience, he compiled, in 1247, the famous *Xi yuan ji lu* (*Collected Records of Washing Away the Wrong Cases*, also translated as *The Washing Away of Wrongs*) which is the earliest work in medico-jurisprudence both in China and abroad. This book has been translated into several Western languages (Jia, 1984).

Song Yingxing and *Tiangong Kaiwu*

Pan Jixing

Son Yingxing (alias Changgeng, 1587-ca. 1666) was a great scientist and thinker of the seventeenth century. He was born in Fengxin county

in Jiangxi province in 1587. After graduating from the county school he became *jüren* or a successful candidate in the imperial examination at the provincial level in 1615. He took part in the highest imperial examinations in Beijing six times, but failed to become a *jinshi*. After that he decided to give up Confucianism and turned to the practical knowledge of natural science. From 1635 to 1638 he taught at Fenyi county school; then he was appointed the prison officer of Tingzhou prefecture in Fujian province from 1638 to 1640. In 1643 he worked as the magistrate of Bozhou prefecture in Anhui province. After the Ming dynasty (1368–1644) was overthrown by Manchu-Qing rulers, Song lived at home as a hermit until his death in about 1666. He had extensive knowledge in both humanistic and natural sciences. He traveled from the south to the north to obtain practical knowledge of agricultural and industrial techniques as well as political and economical information on Chinese society. This made it possible for him to write more than ten books, most of which were completed at Fenyi from 1636 to 1637.

The *Tiangong Kaiwu* (Exploitation of Products from Nature by Means of a Combination of Artificial Skills and Natural Power, also translated as *The Creations of Nature and Man*, 1637) is his most important work. It consists of 18 chapters on 33 departments of agricultural and industrial production including grain planting, sericulture, spinning and weaving, dyeing, salt and sugar making, vegetable oils, distiller’s yeasts, ceramics and porcelain, metallurgy and casting, paper and ink making, coal, alum and copper producing, carriages and shipbuilding, cold weapons and firearms, and pearl and jade exploiting. Apart from detailed descriptions of the above-mentioned techniques, there are 123 useful illustrations in this book. It recorded many advanced technical achievements from the distant past until the Ming dynasty and made a comprehensive generalization them. Some had been rarely talked about in previous works, such as improving paddy and silkworm varieties through artificial hybridization, smelting zinc from calamine, smelting wrought iron from pig iron, producing alloys of copper and zinc, etc.

This work also developed many advanced technical ideas, especially the *Tiangong Kaiwu* thought which emphasized the coordination between mankind and nature as well as artificial skills and natural power in order to exploit various products from nature for people's use.

Not only was the *Tiangong Kaiwu* welcomed in China, but it also spread to Japan and Korea from the seventeenth to the eighteenth centuries and became a popular reference work for Japanese and Korean scholars during the Edo period (1608–1868) and the Yi dynasty (1392–1910). It was reprinted in Osaka in 1771. During 1830–1840 five chapters of it were translated into French, then into English and German. The part on sericulture was cited by Charles Darwin and highly valued. In 1869 many chapters on industrial techniques were collected in the *Industries anciennes et modernes de l'Empire Chinois* published in Paris. The first four chapters on agriculture were translated into German in 1964; 2 years later the whole book was published in English in the United States. It was regarded as an “encyclopédie technique” by French sinologist Stanislas Julien of the nineteenth century, and Joseph Needham, the British scholar, called Song a “Chinese Agricola” or “Chinese Diderot.” It has now become a world-famous classical scientific work.

Among Song's existing works there are also the *Ye Yi* (Proposals to the Court from Common People, 1636), *Si Lian Shi* (Poems on Praising the Good and Pitying the Foolish, 1637), *Lun Qi* (On the *Qi*, 1637), and *Tan Tian* (On Celestial Bodies, 1637). The *Ye Yi* reflected the author's political and economic thought. He put forward a plan of political reform for the Ming court for averting the political and economical crisis in society. He considered that social wealth was created by labor and that currency should not be the definition of wealth. He believed that increasing social wealth meant producing more consumable goods. Therefore, his ideas are similar to those of Adam Smith.

The *Lun Qi* is a work on natural philosophy. It explains the formation and composition of all things by means of a combination of the theory on the *qi* and the new theory of ► [yinyang](#) and

five elements. He introduced a new conception of *xing* (form or shape) between the *qi* and five elements, and he explained the material unity in the composition between organic and inorganic substances. He also discussed the idea of conservation of matter in this work. It also dealt with acoustical problems, and pointed out that the formation of sound is the result of the vibration of substances, and the medium of the spread of sound is the air. Song considered that the spread of sound in the air should be in the form of a water wave; he thus put forward a preliminary conception of a sound wave.

In his astronomical work, the *Tan Tian*, he criticized a traditional theory that the solar eclipse was connected with human affairs. He thought that all things including the sun are always changing. He said: “Therefore, the sun today is no longer the same one as yesterday.” Most of Song's advanced philosophical thought was further developed by another great philosopher, Wang Fuzhi (alias Chuanshan, 1619–1692). Those in academic circles are familiar with his scientific achievements, but much less familiar with his political, economic, and philosophical thoughts, because those works were only found in the mid-twentieth century and have not been carefully studied yet.

Soy Sauce

Hanifah Nuryani Lioe

Department of Food Science and Technology,
Faculty of Agricultural Technology and
Engineering, Bogor Agricultural University, IPB
Campus Darmaga, Bogor, Indonesia

Introduction

The term soy sauce commonly refers to a light- to dark-colored liquid made from soybeans. Soy sauce is a condiment and seasoning which has a savory taste and specific aroma, and it contributes to palatable cuisines in many Asian countries. There are three different categories of soy sauce on the market, according to the production process, i.e., fermented soy sauce, chemical soy sauce, and a combination of fermented and chemical soy sauce (Fukushima, 1981; Hesseltine & Wang, 1980). However, the original soy sauces are usually the fermented ones (Fukushima, 1981).

They started to use chemical soy sauce decades ago; it was made by a rapid acid hydrolysis of soybean proteins. Fermented soy sauce has been produced since ancient times by using microbes to ferment soybeans for months. Traditionally, the fermentation process involves molds at the first stage and then bacteria and yeasts at the next stage under high salt condition.

History

Soy sauce has been traditionally produced since 2,000 years ago in China, where it was formerly called *chiang* and *shih* and then *chiang-yu* in the sixteenth century. This tamari-type soy sauce was introduced into Japan before 700 AD, and in the sixteenth century, the name of *shoyu* was recognized. Chiang-yu in China and shoyu in Japan have the same Chinese characters (Yokotsuka, 1986).

The tamari-type soy sauce was also widely produced in Southeast Asian countries, including

Indonesia, Singapore, Malaysia, Thailand, and the Philippines, previously following the Chinese or Cantonese traditional techniques spread from generation to generation, but since several decades ago applying Japanese modern production techniques. In Indonesia, soy sauce is called *kecap*. But, this term is also familiar to people in some Southeast Asian countries such as Malaysia and Singapore.

Types of Soy Sauce

Soy sauce can be grouped into two types: Japanese and Chinese. Japanese soy sauce uses soybeans and wheat in equal amounts; this type is differentiated further into *koikuchi*, *usukuchi*, and *saishikomi shoyu* in Japan regarding their different production process and product characteristics in color, aroma, and viscosity. Another type of shoyu, *shiro shoyu* (*shiro* means white in Japanese), actually has a very light and transparent yellow color because of the large amount of wheat with very few soybeans. Chinese soy sauce uses no or a small amount of wheat as an addition to the soybeans; this type is called *tamari shoyu* in Japan and has a very dark color.

The type of soybeans used for Japanese soy sauce production is commonly yellow soybeans, while the Chinese type found in Indonesia uses black soybeans. Yellow and black soybeans are of the same species *Glycine max*, but they are different in their outer color.

Traditional Production

In general, there are two steps to the fermentation process in soy sauce production either in traditional or modern industrial production. The first step is solid-state fermentation (typically called *koji* in Japan or *bungkil* in Indonesia) which involves some molds. The second step is brine fermentation (called *moromi* in Japan or *baceman* in Indonesia) at high sodium salt concentrations, ranged 17.5–20 %w/v, by involving some halophilic bacteria and osmophilic yeasts. Molds in the first step are mainly *Aspergillus oryzae*,

Aspergillus sojae, and *Aspergillus tamarii* as found in soy sauce production in Japan, China, and Southeast Asia. Bacteria and yeasts in the second step of fermentation are salt-tolerant lactobacilli, *Saccharomyces rouxii* and *Candida versatilis* found in Japanese soy sauce (Yokotsuka, 1986) and *Pediococcus halophilus*, coryneform bacteria, *Zygosaccharomyces rouxii*, and *Candida parapsilosis* found in traditional Indonesian soy sauce production (Röling, Apriyantono, & van Verseveld, 1996; Röling, Schuurmans, Timotius, Stouthamer, & van Verseveld, 1994; Röling, Timotius, Prasetyo, Stouthamer, & van Verseveld, 1994). In Indonesia, traditional production applied the spontaneous solid-state and brine fermentation.

A study on traditional soy sauce production in Southeast Asia was conducted with Indonesian soy sauce, kecap. The boiled whole soybeans are subjected to spontaneous solid-state fermentation for 1–2 days, and then the resulted bungkil is sun dried and mixed with brine solution (three to four times of volume); afterwards the baceman fermentation stage started for 4 months or less spontaneously. Since ancient times, people used sun drying for the bungkil and the baceman. The sun-dried bungkil gave a faster growth of lactobacilli in the next step of fermentation. The baceman process under the sun could avoid the growth of spoilage microbes at the surface. Otherwise, the salt hygroscopic property might lower the salt concentration at the surface, and therefore lesser salt-tolerant microbes such as film/pellicle-forming yeasts could grow and spoil the baceman (Röling, Timotius, Stouthamer, & van Verseveld, 1994). The salt concentration range could be maintained if the baceman was simply left to be opened under the sun with a periodic mixing.

At the final process of traditional production, the moromi or baceman yielded is then filtered manually or mechanically to obtain a raw liquor. This liquor is then pasteurized and bottled for shoyu before being marketed, or else it is boiled, and then a high amount of brown sugar is added during boiling to produce a thick and sweet soy sauce, called *kecap manis*. Or a very small amount of brown sugar is added to produce a thin and salty soy sauce, called *kecap asin*.

Modern Industrial Production

Modern industrial production has been widely applied for Japanese-type soy sauce production, either in Japan or in Indonesia, which applied the modern soy sauce process technology and used defatted yellow soybean flakes and wheat for raw materials. The modern technology allows a more controlled koji and brine fermentation with the use of pure microbial cultures, temperature controls, and mechanical mixing. The full equipment process for automatic koji preparation replaced the traditional process. The equipment consists of a continuous soybean cooker as well as continuous wheat roaster, automatic inoculators with an automatic mixer, large perforated shallow vats equipped with forced air devices, temperature control device, and mechanical turning device during incubation (Fukushima, 1985). The length of koji preparation, nevertheless, is almost the same as in the traditional process, 48 h.

By the use of modern technology, the length of brine fermentation could be reduced from 1 to 3 years in the traditional shoyu production to less than 1 year (4–8 months) in modern industrial production in Japan (Yokotsuka, 1986). The length and condition of brine fermentation either in traditional or modern production in Indonesia are the same, 4 months and at the same spontaneous condition subject to tropical weather. This is because the soy sauce aroma found in shoyu is less important for Indonesian soy sauce (Röling et al., 1996).

In the final process, moromi filtration using modern equipment with high pressures is applied. Currently, the membrane technology using nanofiltration has been developed to provide the standard color for soy sauce products in modern industries (Miyagi, Suzuki, Nabetani, & Nakajima, 2013).

Chemistry and Biochemistry

Yong and Wood (1977) studied the release of extracellular protease and carbohydrase complex enzymes during koji fermentation. Protease

complexes in koji hydrolyze soy proteins into peptides and amino acids, while carbohydrase complexes hydrolyze wheat carbohydrates into sugars. The ratio of peptides to amino acids in koji is nearly 1:1. The main free amino acids found in koji are glutamine and glutamic acid (Flegel, 1988). Glutamic acid is related to an umami taste (Lioe, Apriyantono, Takara, Wada, & Yasuda, 2005).

In the brine fermentation, lactic acid is produced at the earlier stage by the action of lactobacilli; therefore, the pH of moromi decreases rapidly, and then some phenolic and aroma compounds are formed due to the alcoholic fermentation by osmophilic yeasts at the next stage of moromi production. However, the alcoholic fermentation was not found in Chinese- or tamari-type soy sauce because of the lack of carbohydrate during the fermentation process as a result of the use of different composition of raw materials (Apriyantono, Husain, Lie, Jodoamidjojo, & Puspitasari-Nienaber, 1999). The presence of lactic acid as a dominant organic acid in soy sauce could be used to identify the fermented soy sauce from chemical soy sauce which is dominated by formic acid.

Glutamic acid is the main amino acid in soy sauces and contributes to their intense umami taste. In fact, the use of black soybeans could lower the glutamic acid present in soy sauce, compared to the use of yellow soybeans (Apriyantono, Setyaningsih, Hariyadi, & Nuraida, 2004).

Nitrogenous compounds such as small peptides and free amino acids, as well as sugars, are still present in the final product and contribute to the quality and taste of soy sauce. However, the peptides make a relatively low contribution to the intense umami taste of soy sauce (Lioe, Takara, & Yasuda, 2006). Some dipeptides – Ile–Gln, Pro–Lys, Ile–Glu, Thr–Phe, and Leu–Gln – are clearly found to correlate to soy sauce sweetness (Yamamoto et al., 2014). Japanese-type soy sauce has more esters and phenols as aroma compounds. Volatile organic acids are dominant in Chinese- or tamari-type soy sauce.

Potential Benefits and Risks

The use of soy sauce as an antioxidant in a food system such as raw beef patties has been investigated (Kim et al., 2013). A *kokumi* peptide is also found in soy sauce, i.e., γ -Glu-Val-Gly (Kuroda et al., 2013) at concentrations 1.5–6.1 ppm. The *kokumi* characteristic could contribute to the savory taste of the food.

The use of molds during koji fermentation has become a concern about the mycotoxin in soy sauce. As much as 97.5 % of soy sauces marketed in China were contaminated with deoxynivalenol or DON at concentrations of 4.5–1,245.6 ppb (Zhao, Wang, Zou, & Zhao, 2013). Kojic acid, another mycotoxin, is also produced by *Aspergillus oryzae*, *Aspergillus sojae*, and *Aspergillus tamarii* (Flegel, 1988). Therefore, harmless strains of the molds should be used for soy sauce production.

A high-temperature-derived contaminant, 3-monochloropropane-1,2-diol (3-MCPD), could be found in the half-fermented soy sauce and chemical soy sauce products. This contaminant is formed during the acid hydrolysis of soy proteins by hydrochloric acid (HCl) under a certain condition due to the reaction between HCl and the soybean fat under heat (Nagodawithana, 1995; Nyman, Diachenko, & Perfetti, 2003). 3-MCPD is carcinogenic in human with a tolerable daily intake (TDI) of 7 μ g/kg body weight/day (Rietjens, Scholz, Berg, Schilter, & Slob, 2012). However, 3-MCPD is found even though at a relatively low level in some traditional fermented soy sauces.

Sphujidhvaja

K. V. Sarma
Madras, Tamilnadu, India

Sphujidhvaja was apparently of Greek descent and flourished in Western India under the patronage of the Kṣatrapa ruler Rudradāman II. He wrote the extensive genethliological manual entitled *Yavanajātaka* (Horoscopy of the Greeks) in AD 270, which shows the position and influence

of the stars at one's birth. Toward the close of his work, Sphujidhvaja says that before him, in AD 150, the great Greek genethliologist Yavaneśvara redacted into Sanskrit prose a Greek astrological work, so that it could be studied by those who did not know Greek, and that he, Sphujidhvaja, is composing a versified redaction of the work of Yavaneśvara. The work reveals Sphujidhvaja as a competent scholar, a master of Sanskrit versification, and an expert genethliologist.

Sphujidhvaja states that he composed the work in 4,000 verses. But the only manuscript of the work available today contains only 2,300 verses. In this imperfect manuscript, the first few sections are numbered but not so the subsequent ones, which number, in all, 79. Possibly, several sections are lost. In these 79 sections, the work covers a large number of aspects of horoscopy and natural astrology, including

- Zodiacal signs and planets, their icons, nature, and relationships
- Iconography of *horās* and decons
- Astrology of conception, birth, and nature
- Horoscopes
- Planetary placements and combinations affecting human beings
- Prediction on the basis of questions
- Reconstruction of lost horoscopes
- Omens and dreams
- Military astrology

The several aspects of each of these topics are looked at from different points of view, and intimations, indications, and predictions based thereon are stated categorically.

It is interesting that although based ultimately on a Greek text, there was substantial Indianization effected in the *Yavanajātaka*. This was accomplished by using Indian equivalents to Greek terms, adopting Hindu deities in place of Greek ones, incorporating the names of Hindu castes and professional orders, mentioning local manners and customs, and the like. *Yavanajātaka* was looked upon as authority by all later Indian genethliologists and used as such even in the foremost of Indian texts like *Bṛhajjātaka* and *Bṛhatsaṃhitā* of Varāhamihira,

Sārāvalī of Kalyāṇavarman, *Praśnavidyā* of Bādarāyaṇa, and many others.

The significance of *Yavanajātaka* stems from another point as well. The work refers to contemporary social orders, professions, religious classes and groups, items of ordinary use, manners and customs, dress, and a host of other things related to the life and society of the times. The information provided by the work on these subjects makes it a good source for the study of the culture and civilization of India during the early centuries of the Christian era.

Śrīdhara

R. C. Gupta

The mathematical works of Śrīdhara were very popular and made him quite famous. In spite of his great popularity, some controversies have been raised about his life, work, and time, such

as whether he was a Hindu or a Jain, and whether he wrote before or after ► [Mahāvīra](#) (ninth century AD). Some uncertainties exist because Śrīdhara's works are not fully extant. Often he is confused with other authors of the same name. Here we shall give views which are now generally accepted.

Like so many ancient Indian authors, Śrīdhara did not provide any information about himself in his works. Other sources have not been helpful in finding any glimpse of his personal life. So we do not know his parents or teachers, or even where he was born, educated, or worked. But some evidence shows that he was a Saivite Hindu. An example in his *Pāṭīgaṇita* is about the payment for the worship of the five-faced Hindu god Śiva. He starts his *Triśatikā* with a homage to the same god. However, in a manuscript which has a possible commentary and additional examples written by an apparently Jain writer, the word “Jinam” is found in place of “Śivam”. This led to the claim that Śrīdhara was a Jain, but other evidence does not support this view.

More serious is the controversy about Śrīdhara's time. That he lived after ► [Brahmagupta](#) is evident from the fact that he literally quoted (and criticized) a rule from Brahmagupta's *Brāhmasphuṭa-siddhānta* (AD 628). The most significant question in this connection is whether Śrīdhara wrote before or after Mahāvīra, whose date of ca. AD 850 is certain. There are similarities in the works of these two mathematicians. Most scholars believe that indications generally place Śrīdhara before Mahāvīra. A new fact has come to light recently; David Pingree found that a rule of Śrīdhara's had been quoted by Govindasvāmin (about AD 800–850) in his commentary on the *Horāśāstra* of Parāśara (under 14.97). This latest and direct evidence once again supports the generally accepted view of placing Śrīdhara in the eighth century or ca. AD 750.

Śrīdhara is known to be the author of the following three works on mathematics:

1. *Pāṭīgaṇita* (on arithmetic and mensuration)
2. *Pāṭīgaṇita-sāra* (an epitome of the above)
3. *Bījagaṇita* (on algebra)

The *Pāṭīgaṇita* is a standard Indian treatise on practical mathematics meant “for the use of the people”. It is also called *Br̥hat-Pāṭī* (Bigger Pāṭī) and *Navaśatī* (Having Nine Hundred) because it is believed to have 900 stanzas. Unfortunately, it is not extant in full; the available text contains only 251 stanzas. In terms of topics, treatment of definitions, logistics, mixtures of things, and series are available in full, but that of the plane figures is incomplete. Many other treated topics are mentioned in the list of contents, but they are totally missing from the manuscript. These were excavations, piles of bricks, sawn pieces of timber, heaps of grain, shadows, and the mathematics of zero (whose loss is quite sad).

The *Pāṭīgaṇita-sāra* is also called *Triśatī* or *Triśatikā* because it was a “Collection of 300 verses”. It was the author’s own summary of the larger work on the subject.

Śrīdhara’s *Bījagaṇita* (Algebra) seems to be lost completely. We know about it from a statement of ► *Bhāskara II* (AD 1150) who also quoted a rule from it. The rule gives a method for solving any quadratic equation and has also been quoted by others. Many other rules from different works of Śrīdhara have also been quoted by various writers. This shows the popularity of his works.

A recently discovered work called *Gaṇita-Pañcaviṃśī* is also stated to be from the pen of Śrīdhara, but it may not be his genuine work. Similarly, a number of astronomical, astrological, and other works authored by different persons of the same name have been ascribed wrongly. Confusions were created both by the similarity of names and also by the proximity of their dates.

In India, ten has been the base of counting since very early times. But the number and names of decuple terms used in the decimal numeration were at variation throughout the ancient period. Later on, the decuple terms were used to denote the notational places when the positional system was developed, and their number was standardized to 18 (which was a traditionally sacred number). Śrīdhara gave a definite list of 18 terms which became standard in Indian mathematics. It runs thus: *eka*, *daśa*, *śata*, *saharsa*, *ayuta*, *lakṣa*, *prayuta*, *koṭī* ($=10^7$), *arbuda*, *abja* (or *abda*), *kharva*, *nikharva*,

mahāsaroja, *śaṅku* (or *śankha*), *saritāmpati*, *antya*, *madhya*, and *parārdha* ($=10^{17}$).

Among the arithmetical rules discussed in the *Pāṭīgaṇita*, *Sūtra* 49–50 gives a formula for finding the time in which a sum lent out at simple interest will be paid back by equal monthly installments. Under the *Sūtra* 63–64 he presents the famous problem of a Hundred Fowls, in which we have to solve the indeterminate equations in integers. [The hundred fowls problem goes like this: Roosters cost three coins each chicks are three for one coin. If 100 fowls are purchased for exactly 100 coins. Then how many of each are bought?]

For mensurations related to a circle, Śrīdhara used the approximation $\pi = \sqrt{10}$, a very ancient Indian value. But there is some evidence to show that he used $\pi = 22/7$ in the lost part of *Pāṭīgaṇita*.

Another of Śrīdhara’s great achievements was his mensuration of the volume of a sphere.

Śrīpati

Kripanath Sinha

Śrīpati was the most prominent Indian mathematician of the eleventh century. He was the son of Nāgadeva and lived in Mahārāṣṭra. He flourished during the period from AD 1039 to 1056.

General appreciation for Śrīpati's fame as a mathematician is based on his arithmetic, *Gaṇitatilaka*, and the two mathematical chapters of his astronomical work entitled *Siddhāntaśekhara*. The 13th chapter, the *Vyktagaṇitādhyāya*, contains arithmetical rules, series, mensuration, and shadow reckoning. The 14th chapter, the *Avyktagaṇitādhyāya*, is one of the few extant Hindu works on algebra. The only edition (by Kapadia) of the *Gaṇitatilaka* contains a valuable commentary by Sihatilaka (ca. AD 1275).

Besides including in his works selected rules of his predecessors, Śrīpati enriched Indian mathematics by giving some improved and some original rules. The *Gaṇitatilaka* contains the earliest known treatment of simple addition and subtraction in any Indian work. Also included is the earliest version of our angular method of addition used to check the accuracy of a sum and simplify addition. The *Vyktagaṇitādhyāya* gives an improved rule for the volume of an excavation.

The *Avyktagaṇitādhyāya* contains most of Śrīpati's original ideas and rules. In it, he presents the idea of an extensive system of symbolism in algebra, the only Hindu treatment of the cubing of signed numbers, and explicit recognition of the nature of imaginary quantities that is second only to Mahāvīra's. He also provides the earliest versions of our ordinary method of solving simple linear equations by using inverse operations and an early formal treatment of factorization. The rules not only give the ordinary method of factoring based on successive division, but also provide an additional method for factoring a nonsquare number by expressing it as the difference of two squares.

Śrīpati also displayed his mastery of indeterminate equations by giving an improved rule for solving the factum and original rules for solving the pulverizer. He also described an original method to obtain rational solutions of the square-nature.

All Śrīpati's works are in verses. The *Siddhāntaśekhara* contains only rules, but the *Gaṇitatilaka* is written in an autocratic style of teaching strategy, in which a rule is followed by plentiful exercises. The book is quite secular in nature. According to the author's testimony, it was written for public use. It contains arithmetical and commercial rules, and some problems solvable by simple linear, quadratic, and radical equations. A garland problem and numerous other fanciful problems included in the book make it pleasurable and interesting. The practical and aesthetic values of the *Gaṇitatilaka* cannot be underestimated.

Śrīpati, however, also had some weaknesses. His mathematics of division by zero is all wrong. In the *Vyktagaṇitādhyāya*, he uses the term *caturbhujā* to mean a square, a quadrilateral in general, a cyclic quadrilateral, a quadrilateral with equal altitudes, and an isosceles trapezoid. Because of this inconsistency, his rules on mensuration of quadrilaterals are hard to interpret.

Šā'id al-Andalusī

Sema'am I. Salem

Abū al-Qāsim šā'id ibn Abū al-Walīd ibn 'Abd al-Raḥmān ibn 'Uthmān al-Taghlibi, better known as šā'id al-Andalusī or Qāḍi šā'id, was

born in Almeria in southern Spain in AD 1029. He was a philologist, natural philosopher, and historian as well as judge. As his name indicates, he was a member of the tribe of Taghlib, one of the largest tribes of Arabia. When the Arabs invaded Spain in AD 711, members of this tribe entered the country and prospered there.

ṣāʿid was born into a well-to-do family, whose members spent much of their time and wealth in the quest of knowledge and education. His father occupied a highly respected position in the city of Cordoba, and his grandfather, ʿAbd al-Raḥmān, was a judge in Sidonia, Spain. After receiving his early education in Cordoba, ṣāʿid toured Muslim Spain to further his education. For the same reason, at the age of 17, he moved to the city of Toledo.

Like most young Arab students, ṣāʿid studied law, Islamic religion, Arabic language, and Arabic literature. Later in life, he specialized in the study of mathematics and observational astronomy. Among his most famous teachers were al-Fātiḥ Muḥammad ibn Yūsuf (d. AD 1059), Abū Walīd al-Waqshī (d. AD 1059), and Ibn Idris al-Tajībī, who taught him mathematics and astronomy.

Early in the eleventh century, Cordoba ceased to be the principal intellectual center of Spain, and the capital cities of the *Mulūk al-Ṭawāʾif* (party-kings) tried to capture its former glory. One such city was Toledo, the capital of the principedom of Banū al-Nūn. When ṣāʿid entered Toledo, it was governed by Yaḥyā ibn Dhi al-Nūn (r. AD 1037–1074) and extended his kingdom to include Valencia and most of the eastern parts of Andalusia. During his reign, Toledo became an important literary and intellectual center. In addition to several authorities in Islamic sciences, Yaḥyā's court had several good mathematicians, well-known astronomers and astrologers, several men of medicine, poets, and geometers.

The number of eminent scholars, poets, and philosophers in a ruler's court was one of the status symbols of the time. Probably for that reason, Yaḥyā invited ṣāʿid into his court and appointed him a judge (*qāḍī*).

Several of ṣāʿid's students later became accomplished scholars. Among them was ʿAbd

al-Bāqī ibn Baryal, who was in part responsible for the style and language of some of ṣāʿid's writing. There was also the outstanding astronomer and mathematician Abū Ishāq al-Zarqālī (Arzaquiel) who, with the assistance and the guidance of his mentor, constructed the famed Toledan Tables. These astronomical tables, which were accurate calendars, were translated into Latin by Gerard of Cremona, and became the basis for the Marseilles Tables.

ṣāʿid wrote several manuscripts on a variety of subjects. All of his works except for *Ṭabaqāt al-ʿUmam* (Book of the Categories of Nations) are lost. He mentioned in *Ṭabaqāt al-ʿUmam* that he wrote a document on observational astronomy, one on the history of nations, and another on their religions. He may have written a manuscript on the history of Andalusia and one on the history of Islam. *Ṭabaqāt al-ʿUmam* is an authoritative source and a precise reference that identifies the natural philosophers of Muslim Spain.

ṣāʿid died in July, AD 1070. Ibn Yaḥyā al-ḥadīdī, the most illustrious dignitary in the court of Ibn Dhi al-Nūn, read his official obituary.

Stars in Arabic-Islamic Science

Paul Kunitzsch

University of Munich, Munich, Germany

The Arabs in pre-Islamic times – mostly Bedouins in the Arabian Peninsula – already had a good knowledge of the stars. They used certain stars or asterisms for orientation in their desert

travels, to fix seasons, and to predict weather, especially rain. For the last two purposes, they developed a system of so-called *anwāʾ* (sing. *nawʾ*), in which a star or asterism was observed setting shortly before sunrise and another simultaneously rising, just opposite (the latter one was called *raqīb*, with respect to the first one). At an unknown time and through unknown channels they received – most probably from India – the system of the 28 lunar mansions (*manāzil al-qamar*), stars, or asterisms along the path of the moon, near the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). The indigenous *anwāʾ* were then merged with the lunar mansions, and the 28 mansions were given names from among the former *anwāʾ*. All the five planets visible to the naked eye seem to have been known, since the Arabic language has old indigenous names for them: Mercury, *ʿuṭārid*; Venus, *al-zuhara*; Mars, *al-mirrīkh*; Jupiter, *al-mushtarī*; and Saturn, *zuḥal*. Also, fragments of the Babylonian zodiac seem to have reached the Arabs in pre-Islamic times, though their location in the sky was different from that in Babylonian and Greek (and modern) astronomy; the figure corresponding to Gemini (*al-jawzāʾ*), for example, was located in the stars of Orion, or the figure corresponding to Aquarius (*al-dalw*) in the Pegasus square. Such star lore was also much used in classical Arabic poetry, in pre-Islamic times, and afterward. From the ninth century on, Arabic lexicographers and philologists collected the dispersed elements of old Arabic folk astronomy and put them together in special monographs (called *Kutub al-anwāʾ*, Books of the *anwāʾ*). From these, more than 300 old Arabic names for stars and asterisms could be recovered.

A new development began after the Muslim conquest of the lands of the Middle East. Now the Arabs came into contact with Greek science as transmitted and practiced in learned circles, mostly by Christian monks and scholars, in the area. After a period of undocumented first contacts, from the eighth century on, Greek scientific texts were translated into Arabic in great numbers. Scientific astronomy in the Islamic world therefore was largely built on Greek knowledge,

with additional elements received from India and Persia. Greek cosmology and Greek theories of the planets, the fixed stars, and other celestial phenomena formed the basis of Arabic-Islamic astronomy. Later Muslim astronomers continued to work with this material, developed it, and introduced many corrections and improvements. But the “Copernican Revolution” did not reach the Islamic world; Arabic-Islamic astronomy continued to be Ptolemaic into the nineteenth century.

On the (fixed) stars, the main source for the Arabs was Ptolemy’s *Almagest*, which contains in Books VII and VIII a catalog of 1,025 stars arranged in 48 constellations and listed with their ecliptical coordinates, longitude and latitude, and magnitude. These 48 constellations (which also live on, in modified form, in modern astronomy) and the derived nomenclature of the 1,025 known stars were used by Muslim astronomers through all times, in books as well as on instruments (astrolabes, celestial globes, quadrants). To make the catalog valid for all times, Ptolemy proposed to add to the longitudes of the stars a constant of 1° in 100 years, to correct for precession. The Muslim astronomers very soon (in the ninth century) found a better value, 1° in 66 years, later also 1° in 70 years, and other values were used. The pictorial figures of the constellations were also basically taken from Greek models; only details of the physiognomy of human figures and clothing were more or less adapted to contemporary local styles.

The main Arabic work on the fixed stars and the constellations was the *Book on the Constellations* by the Persian astronomer Abu’l-ḥusayn al-Šūfī (903–986); al-Šūfī anxiously followed the Arabic versions of the *Almagest*, added criticisms based on his own observations, but established his star catalog exactly according to the data given in the *Almagest* (adding a constant of $12^\circ 42'$ to the longitudes, for precession, for his epoch AD 964). For each constellation, al-Šūfī added two drawings, one showing the figure as seen in the sky and the other showing it as seen on the celestial globe (in reality, however, the figures simply appear as seen in a mirror, with the right and left sides reversed). Most Islamic globe

makers, through all centuries, followed al-Šūfī's models in depicting the constellation figures.

Several Islamic astronomers established star catalogs in the manner of the *Almagest*: al-Battānī (epoch 880, precession constant added $11^{\circ}10'$), al-Šūfī, al-Bīrūnī (epoch 1031, precession constant $13^{\circ}0'$), and Ulugh Beg (epoch 1437, own observations but some stars taken over from al-Šūfī). Besides these big catalogs, smaller star lists were drawn up by very many astronomers, for use on astrolabes or other instruments. Most of the catalogs and star lists, however, were not obtained through observation; they were adapted from the *Almagest* or derived catalogs by adding the precession constant to the longitudes. A small list of 24 stars obtained through independent observation was established by the astronomers of the caliph al-Ma'mūn for the epoch 214 Hijra = AD 829–830; also other star tables were afterward derived from it by adding the precession constant.

Other celestial phenomena, such as comets or meteor showers, were not considered by the Arabic-Islamic astronomers. Following Greek cosmological theory, they supposed these to belong to the sublunar sphere, i.e., the space between the Earth's surface and the moon, and not to the sphere of the stars. The fixed stars in their opinion were all situated on the farthest, eighth sphere, beyond the seven spheres of the planets and the sun and moon. It was mostly in chronicles and in astrological works that such phenomena were registered, and they were usually regarded as bad omens indicating evil events.

Through Latin translations in late tenth and mainly in the twelfth century in Spain, many star names of Arabic origin entered the West and continue to be used in Western astronomy, mostly in heavily distorted spellings, today.

Stars in Chinese Astronomy

Sun Xiaochun

In Chinese astronomy, stars were called *Hengxing* (fixed stars) or *Jingxing* (warp stars), while planets were called *Xingxing* (movable stars) or *Weixing* (web stars). The traditional Chinese sky was composed of 283 constellations which included 1,464 individual stars. This unique system was first established by Chen Zhuo, an astronomer of the Three Kingdom period (AD 220–280), who collected knowledge about stars from the Han time and summarized it in a new catalog of stars. According to Chen Zhuo, these constellations belonged to three separate astronomical schools: 93 constellations belonged to Shi Shi (Master Shi), 118 to Gan Shi (Master Gan), and 44 to Wuxian Shi (Master of Wuxian). There were also 28 lunar mansions (*Xiu*), which were very important in the Chinese sky. Stars of the three astronomical schools were preserved in the *Kaiyuan Zhanjing* (Treatise on Astrology) of the Kaiyuan period (AD 729) from the Tang Dynasty (AD 618–907). After Chen Zhuo little was changed of the Chinese system of constellations.

The observation of stars started as early as civilization began. Among the oracle bone inscriptions from the Shang Dynasty (ca. sixteenth–eleventh centuries BCE) some stars were mentioned. In the *Shangshu* (Historical Classic), the paragraph concerning four cardinal asterisms has generally been agreed to be the record of the observation of stars from before the twenty-first century BCE. But before the Han Dynasties (106 BCE–AD 220), no description of the total sky existed; only 38 star names were mentioned in pre-Han literature. These stars were either of the 28 *Xiu* or were very popular stars such as *Beidou* (Ursa Major), *Niulang* (α Aql), and *Zhinü* (Vega, α Lyr). They appeared in folklore and poems. During the Warring States period (480–222 BCE) there lived two famous astronomers, Shi Shen and ► [Gan De](#),

who were founders of two of the abovementioned astronomical schools. But what were called Shi Shi's and Gan Shi's constellations did not seem to exist in their own time; they were later developments of the nomenclature of stars during the Han. The earliest descriptions of the total sky was in the *Tianguan Shu* (Monograph on Heavenly Officers) by Sima Qian (145–86 BCE) in which 91 constellations including about 500 stars were mentioned. The earliest star catalog, giving coordinates of 92 leading stars of Shi Shi's constellations and of 28 determinative stars of the 28 *Xiu*, were observed a few decades after Sima Qian. That is, the evidence shows that Shi Shi's constellations were scientifically established during the Former Han (206 BCE–AD 25). Shi Shi's constellations consisted of the brightest stars in the sky. They served as the referential system to constellations of other schools. Most constellations of Gan Shi and Wuxian Shi were just fill-ins among Shi Shi's constellations. It is quite certain that the constellations of the three schools obtained their complete forms during the Han times. Chen Zhuo's work was to summarize them.

Constellations in the Chinese sky are much smaller than the Greek ones. A constellation usually includes several stars linked together with imaginary lines. Some constellations are even composed of single stars. Constellations were called inner ones or outer ones according to their location to the North or South of the equator.

The 28 *Xiu* were the basis of the Chinese sky. They spread near the equator and served as one of the dimensions of the Chinese polar-equatorial coordinate system. One coordinate corresponding to the Right Ascension was given as the hour distance to the determinative star of a certain *Xiu*, which was almost always the most western star in the *Xiu*. With great circles linking the determinative stars and the North Pole, the celestial sphere was divided as segments of an orange. Constellations were described in the sequence of the *Xiu* as they were located.

Historical research shows that the 28 *Xiu* are much earlier than the whole constellations of the three astronomical schools. Some star names seemed to be direct derivations from the

mythological, legendary, or astrological meaning of the *Xiu*. A complete set of the names of the 28 *Xiu* was discovered on a lacquered box cover excavated from a tomb dated from 433 BCE. The *Xiu* were formed into four groups of seven which were called Four Images. The Four Images corresponded to the four cardinal points in the sky and the four seasons of the year.

Ancient India and the Islamic world also had similar lunar lodge systems. It is certain that these three systems were originally related. But when and where they were first constructed and how they diffused is still an unsolved problem.

Another feature of the Chinese sky is the existence of the three-wall system. There were three enclosed areas in the sky: *Ziwei Yuan*, *Taiwei Yuan*, and *Tianshi Yuan*. The meaning of *Yuan* is a wall, which was formed by stars surrounding the enclosed area. *Ziwei Yuan* indicated that polar area which included 15 constellations, and the wall was formed with 15 stars. *Tianshi Yuan* and *Taiwei Yuan* indicated two other groups of constellations between *Ziwei Yuan* and the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). The former had 13 constellations, and the wall was formed with 22 stars; the latter also had 13 constellations, but the wall was formed with 10 stars. The names of the three-wall system might have existed early, but their use to indicate groups of constellations was rather late, probably after Chen Zhuo.

Since the Tang Dynasty, the three *Yuan* and the 28 *Xiu* became the main structure by which the stars were organized. The famous astronomer ► [Li Chunfeng](#) (AD 602–670) used this system to describe the sky in *Jinshu Tianwenzhi* (The Astronomical Chapter of the History of the Jin Dynasty, AD 265–420).

The names of the Chinese constellations provide a unique document to be studied. The way stars were named was completely different from the Greek. Stars were organized into a heavenly human society. In the sky you can see:

- Emperor, queen, and princes
- Royal court and clan
- Imperial bureaucracy and administration

- All kinds of buildings and facilities, even a toilet in the sky
- Military installation, armies, and weapons
- Traffic and transportation
- Rituals, ceremonies, and pictures of social life
- Philosophical and religious concepts
- Mythological and legendary figures
- Local states and geographical features

It is a total cultural complexity projected in the sky. In the polar area, for example, the *Ziwei Yuan* was furnished with an emperor, queen, princes, royal high-ranking officials, and facilities in a court. There was one constellation called the North Pole, *Beiji*, the brightest star of which was called *Di* the Emperor. The *Ziwei Yuan* was just like a royal palace; it took the polar area and all the stars turned round it. It reflected the social order of the imperial society of ancient China, as Confucius analogized: “He who is a governor because of his Virtue may be compared to the North Pole Star, sticking to its place and all stars turning about it.” In other parts of the sky, social life pictures were reflected. The *Tianshi Yuan* was a heavenly market, in which all kinds of shops were marked. The Autumn harvest of peasants, the imperial hunt ceremony, and cavalry troops could also be found in the Chinese sky.

Because the appearance of a certain part of the sky is related to seasons, and because it also changes with the precession of the sky, seasonal considerations may help to estimate the time when these earthly happenings were projected in the sky. By and large this practice happened during the Han and was carried on with the impetus given by the philosophy of *Tian Ren Gan Ying* (The Interaction between Heaven and Human Beings) which came to a climax during the Han and which urged a new type of astrology by means of division of the sky. The sky was constructed as a heavenly imperial society so that astrologers could interpret imperial society straightforwardly in correlation with the terrestrial society. Stars in the Chinese sky provided a basis for ancient Chinese astrology.

Throughout the history of China, there has been continuous observation of stars. Although the constellations have been kept basically

unchanged, new measurements of the position of the stars were made in almost every dynasty. Star maps were made to study the sky. The earliest existent star map is from the *Dunhuang* collection of manuscripts of the Tang Dynasty. More accurate and scientific star maps are from the Song Dynasty (AD 960–1279). The Suzhou Astronomical Chart on a stone plate made in AD 1274 is well known. Almost all stars in the Chinese sky were carved quite precisely on the planisphere. The star map was based on the observations made during the Song. Even the supernova of the year of 1054 in Taurus was marked on the star map.

Since the late Ming Dynasty (AD 1368–1644), European astronomy began to influence China. Star catalogs and star maps were made in the way Westerners did. Traditional stars were identified with the sky and more stars were observed. But the framework of the traditional constellations was not abandoned. Newly measured stars were counted as supplementary stars in old constellations. New constellations were added only in the southern sky, where stars had not been registered by ancient Chinese astronomers. The pioneer work of this kind was done by Xu Guangqi (AD 1562–1633) and the German Jesuit Adam Schall von Bell (AD 1592–1666) in *Chongzhen Lishu* (Calendrical Treatise of Chongzhen Period, AD 1628) at the end of the Ming Dynasty. In this book, 23 new constellations including 126 stars were constructed in the southern hemisphere of the sky. Their work paved the way for the Chinese sky to be absorbed into world astronomy.

Steam Power in China

Hsien-chun Wang

Institute of History, National Tsing Hua University, Hsinchu City, Taiwan

The power that drove the machines of the Industrial Revolution was produced by the steam engine's valved piston-cylinder mechanism, which turned the pressure differential within and without the cylinder into a motive force. Its success relied on machine tools that produced metal parts with precision and thermodynamics that facilitated the accurate calculation of heat and motive force. Although premodern Chinese blacksmiths' wooden double-acting piston bellows shared a similar mechanism, human arms were the source of their power (Needham, 1962, pp. 136–137). Previously, China had not had a strong tradition in using metal cutting machine tools. Nor was the Chinese understanding of the atmosphere and heat expressed in mathematical formulae. Therefore, the transfer of steam engine technology faced great technical and scientific challenges. The process of adaptation began with Chinese encountering paddlewheel steamships.

From the late 1820s to the mid-1830s, several foreign steamships visited the port of Guangzhou, south China. The sight of smoke puffing out of the novel vessels' funnels and their rotating paddlewheels attracted attention. In 1828, an anonymous Chinese observer described that a flame fed by burning coal in a copper cylinder drove the paddlewheels. During the Opium War (1839–1842), in which British firearms and steam gunboats defeated Qing troops and war junks, the government officials who witnessed the British steamers gave similar accounts. Their misunderstandings led to a few failed attempts to build paddlewheel boats to fight against the British fleet. Having discovered that smoke had no effect, the Chinese inventors adopted a traditional technology, the treadmill mechanism, to build water wheel boats (*shuilunchuan* 水輪船), a type of treadmill paddlewheel boat that could be traced to the twelfth century. Probably for that reason, the Chinese named the steamer as “fire wheel boat” (*huolunchuan* 火輪船). As late as 1842, a Qing senior official who boarded a British steam warship reported to the emperor that the paddlewheels were driven by fire according to the principle of the clock (Wang, 2010).

Unable to understand the steam mechanism, Qing government officials sought foreign expertise. In early 1842, a Guangdong merchant commissioned foreign technicians in Macau, a Portuguese colony, to build a steamer and donated it to the government. Although the emperor forbade the pursuit of the technology because of its high cost and dubious effectiveness, in 1845, a senior official in Guangdong recruited an American shipwright to build a steamer. Unfortunately, the building work halted after the shipwright died. Qing government officials did not experiment further with steamship technology until the early 1860s.

However, not all Chinese people misunderstood the steam mechanism. Ding Gongcheng, a merchant interested in gunnery, figured out the steam mechanism when he was living in Guangzhou. His book, *Yanpaotushuo* (Illustrative Treatise on Gunnery), printed in 1841, contained an essay describing his experiments with the steam

engine. According to the essay, Ding hired an artisan to build a model locomotive, which was nearly 1.9 ft long and 7.6 in. wide. He used the same engine to build a model steamboat, which was 4.4 ft long and 1.6 ft wide. Both models ran well. Ding admitted that a full-scale steamer could not be built due to the lack of proper tools. His friend Zheng Fuguang tried to figure out the steam mechanism by studying diagrams and a model steamer but did not conduct any experiments. In his essay on the paddlewheel steamer, which was included in his 1846 book on optics, he correctly described the mechanism. Although Ding and Zheng's writings circulated among the Chinese literati, there is no evidence that anyone else learned about the steam mechanism from those essays.

After the war, the Chinese people had more opportunities to observe the steam engine, because, with the opening of five ports to foreign trade, more foreign steamers were visiting China. Additionally, foreign-owned machine shops and dockyards were set up in the treaty ports to service those vessels. In Shanghai, the number of dockyards rose from one in the late 1840s to nine in the 1860s. By 1860, three docks were operating in Hong Kong and four near Guangzhou. Those dockyards hired foreign technicians and Chinese workmen (Xin, 1999, pp. 34–36, 40–42).

Furthermore, because of the Protestant missionary publications in the treaty ports, which aimed at converting Chinese people to Christianity by introducing general knowledge of Western science and technology, Chinese literati had greater opportunity to learn about the steam engine. For example, *Xia'erguanzhen* (Chinese Serial), which began publication in Hong Kong in 1853, and *Bowuxinbian* (Natural Philosophy), which was first published in Guangzhou but after 1855 in Shanghai, contained short essays about the steam engine. Some of the dockyards became leading private shipbuilding enterprises of the Far East in the late nineteenth century. Those changes were the background of the first Chinese-built steamer in the early 1860s.

Two more wars aggravated Qing China's need for steam technology. In the Taiping Rebellion (1851–1865), which was one of the most

devastating civil wars in Chinese history, Western firearms and steam gunboats proved the key factor that decided the results of battles. In the Second Opium War (1856–1860), the Anglo-French allied forces overwhelmed Chinese defenses and seized the capital Beijing, forcing the Qing court to flee. Only in such a critical situation did senior officials call for self-strengthening with foreign firearms and steamships (Kuo & Liu, 1978). In 1861, Zeng Guofan, a leading anti-Taiping commander, recruited Hua Hengfang and Xu Shou, two literati interested in mathematics and chemistry, into his staff and instructed them to experiment on building steamships. They learned the basics of the steam mechanism from the sketchy description published in the *Bowuxinbian* and observed the steam engines on board foreign steamers. After building a model steam engine and a test steamboat, they completed in 1863 the *Huanghu*, which was fitted with a high-pressure engine and a tubular boiler, without foreign assistance (Wang, 2010).

After the Taiping rebels were defeated, the Qing government established modern arsenals that employed steam-driven machine tools. Among these arsenals, the Jiangnan Arsenal (*Jiangnanzhizaoju*, 江南製造局) was one of the foremost firearm manufacturers and shipyards in nineteenth-century China. The arsenal was established in 1865 by Li Hongzhang, Zeng Guofan's lieutenant in the anti-Taiping campaign, on the basis of a foreign-owned machine shop. Zeng, who took over the Arsenal from Li, added the metalworking factory, the boiler shop, the foundry, the dock, as well as the fitting and setting-up shop to its facilities in order to build steamers. The Arsenal recruited foreign technicians to direct Chinese workmen, who, in 1869, numbered 1,000. In 1868, it built its first paddlewheel steamboat, which was fitted with a refurbished 150-hp steam engine. The Arsenal also built five screw-propelled steam gunboats and their engines by 1876. After that, it focused on firearm manufacture but also completed one steel-hull gunboat in 1885 before it suspended its shipbuilding program (Xin, 1999, pp. 107–118).

Although the Jiangnan Arsenal had made some technical progress, a more complete

program for the wholesale transfer of steamship-building technology from its theoretical foundation to its application was established in the Fuzhou Navy Yard (*Fuzhou chuanzheng*, 福州船政局). The Navy Yard was established in 1866 by Zuo Zongtang, another senior official who rose to prominence in the Taiping Rebellion. It had four major workshops: the metalworking shop, the boiler shop, the fitting shop, and the foundry. These shops could produce every part of a steamer, from the engine to the barometer, from raw materials. It recruited a team of 75 French managers and technicians, including the French naval officer Prosper Giquel, to direct Chinese workers in the ship and engine building works. By 1868, the Navy Yard employed as many as 3,000 Chinese workers who were given on-the-job training in drafting, carpentry, machine tool operating, and metalworking. It completed its first screw-propelled steamboat (223 × 29.5 × 13.2 ft dimension, 1,450 t displacement, 150 hp single-cylinder engine) in 1869 and, by the end of 1870, built four more similar vessels. It completed its first domestically built engine in 1871 (Pong, 1994, pp. 203–244).

In order to train naval officers and marine engineers, the Navy Yard established the Fuzhou Naval School (*Chuanzhengxuetang* 船政學堂), which had two divisions: the school of navigation and the school of naval construction. The latter recruited French teachers to teach French, arithmetic, and geometry to students as a prerequisite for physics, descriptive geometry, trigonometry, analytical geometry, calculus, and mechanics. The students were also required to gain practical experience by participating in the shipbuilding works. The number of the students was not large. By 1874, 39 students attended the school. Although the students managed to design and direct the building of a small steamboat without the French technicians' assistance in 1876, the naval yard considered the technological environment of China could not make them competent engineers. Hence, in 1877, it sent some of the students to Europe for further training.

After the expiry of the contract with the French technicians in 1874, the Navy Yard continued to upgrade its technology. Between 1877

and 1880, it completed five ships fitted with the 750 hp compound engine, which was much more sophisticated than the single-cylinder reciprocating engine it had built before. Then, it further introduced the triple expansion engine and, between 1883 and 1886, completed three cruisers that were fitted with purchased 2,400 hp engines of such a kind. It also introduced steel-hull construction and, between 1888 and 1907, built 13 steel-hulled warships. Then, it ceased to build any ships because government funding stopped. In total, the Navy Yard completed 40 steam warships and merchant ships (Wang Zhiyi 1986, p. 99, 110).

The demise of the Fuzhou Navy Yard did not mark the end of China's steamship-building ambitions. The Jiangnan Arsenal's shipbuilding arm became the independent Jiangnan Dockyard in 1905, which recruited a team of foreign technicians to take over the managerial and technical works. It became a successful government-owned enterprise through competing in the shipbuilding business by accepting orders from the Chinese or foreign governments as well as shipping companies. It built sea-going cargo ships and also small displacement gunboats and cargo barges.

Beyond arsenals and shipyards, steam power was mainly used in the shipping business, which was booming after the 1860s, when the conflicts with Britain and France were resolved and the civil war ended. In 1872, when the first Chinese steam navigation company was formed, there had been as many as 13 foreign shipping companies, mostly American and British, operating in Chinese waters (Zhu, 2008, p.4). The number of companies and mercantile steamers fluctuated, but in 1893, the three largest operators, the China Merchants' Steam Navigation Company, the China Steam Navigation Company, and the Indo-China Steam Navigation, had 26, 29, and 22 steamships respectively (Liu Kwang-ching, 1959, p.448).

In comparison, however, the railway industry grew slowly. From the 1860s, the Qing government had rejected foreign diplomats' lobbying for allowing foreigners to build railways (Kent, 1907, pp. 1–8). In 1876, a group of foreign

merchants built a 9½ mile long light railway in Shanghai without obtaining official permission. After negotiation, the Qing government purchased the line and moved the equipment to Taiwan. Unfortunately the line was never rebuilt due to lack of funds (Pong, 1973). In the 1880s, railway building was still a controversial issue in politics. Yet, after the Sino-French War (1884–1885), the Qing government acknowledged the strategic importance of the technology and hence gave the power of managing railway building to the newly established Admiralty (*Haijunyamen* 海軍衙門). However, due to financial difficulties, the speed of construction remained slow. By 1895, only 650 miles of railway lines were completed, but the speed of development increased thanks to foreign loans. By the time the dynasty collapsed in 1910, 5,606 miles more lines had been constructed (Chen, 1981, pp. 6–9).

Because of the need for fuel and raw materials, the Qing government sponsored the opening of coalmines and iron mines with steam power. The Kaiping Coalmine in Zhili province and the Han-yang Iron Works in Hubei province were established in 1871 and 1890, respectively (Carlson, 1971; Quan, 1972). Those enterprises were profitable and survived well into the first half of the twentieth century. The Qing government officials were also willing to sponsor steam power in textile manufacturing. It established two cotton weaving and spinning mills, Shanghai Cotton Cloth Mill (1876) and Hubei Cotton Cloth Mill (1889), and one mechanized woolen mill in Lanzhou, Gansu province (1880). In total, by 1910, the Qing government set up 69 arsenals and factories that employed steam power.

In the private sector, before 1895, Chinese or foreign entrepreneurs were slow to exploit steam power for legal reasons. The Treaty of Tientsin [Tianjin] between China and foreign powers only stipulated that foreigners were allowed to build residential houses, churches, hospitals, and graveyards. Accordingly, the Qing government forbade foreigners from establishing factories in China. Yet, it only prosecuted the key industries mentioned above but ignored those small factories such as a mechanized soybean oil mill in

Niuzhuang (1868–1970) or flourmills in the treaty ports (Wang, 2013). The best available data suggest that by 1895, 88 mechanized factories had been established in the treaty ports (Feuerwerker, 1980, p. 29). The legal constraint was lifted by the Treaty of Shimonoseki (1895), which concluded the Sino-Japanese War (1894–1895), and allowed foreigners to establish factories. Thereafter, 136 more steam-powered factories were founded between 1895 and 1913 (Feuerwerker, 1980, p. 29).

The introduction of the theoretical knowledge of the steam engine to the wider Chinese public was achieved in a limited scope and depth by translation. In 1860, the Qing government established the School of Combined Learning (*Tongwen guan* 同文館) in Beijing for training translators. Apart from teaching foreign languages, it offered courses in Western science and technology. The textbook, *Natural Philosophy* (*Gewu rumen* 格物入門), gave an introduction to the atmosphere and its pressure. It also explained how steam pressure might be turned into motive force by the cylinder-piston mechanism. Furthermore, more books about the steam engine were translated by the Translation Bureau (*Fanyi guan* 翻譯館), which was established in 1868 within the Jiangnan Arsenal for translating books about Western science and technology (Reardon-Anderso, 1991, pp. 29–52; Wright, 2000, pp. 24–127). By the end of the nineteenth century, five translations of marine engineers' manuals or textbooks had been produced. All of these publications were reprinted and circulated among Chinese literati, but none of the publications were included in any coherent technical course that educated engineers. Moreover, readers who did not have basic schooling in modern science and mathematics would find it difficult to gain the competence in the calculation of heat, pressure, and mechanical force, even if formulae were printed in the books. Isolated translations could not produce competent engineers any more than the school of naval construction at the Fuzhou Navy Yard.

A radical educational reform took place in 1904. The Qing government abolished the imperial examinations and started to formulate

a modern system of education after the Western model. Public and private technical schools were established to provide technicians and engineers for the growing industries. Universities were also formed to house engineering departments and foreign professors were recruited. Private publishers which saw the commercial prospects of the reform started to produce translations of textbooks in the fields of modern science and technology at a much larger scale. These educational institutions would provide a greater number of engineers and technicians to China's industrialization.

To conclude, the introduction of steam power between 1838 and 1911 effected a great transformation of technology in China. Although the Chinese people initially misunderstood the steam mechanism, they experimented on it and successfully built a full-scale steamer. After trial and error, the Qing government realized that the existing technical expertise and tools were not enough to build more than one steamer and one engine. Hence, it established modern arsenals and navy yards that employed foreign technicians and imported machine tools. They made good technical progress by the end of the dynasty. They also trained Chinese workmen and a small number of engineers. However, financial difficulties hampered development until they were allowed to enter the market for profits. Although the Qing government intended to introduce the theoretical knowledge about the steam engine to the Chinese literati, that impact was limited.

From the early twentieth century, China underwent an industrialization in which the steam engine was the dominant source of motive power, although different types of motive force, such as the internal combustion engine and the electrical motor, were simultaneously introduced. According to an industrial survey conducted in 1937, 86 % of motive force in terms of horsepower in China's factories was steam powered (Liu Dajun, 1994, p. 96, 128, 160). More than 50 % of electricity was generated by coal-fired steam turbines (Tao Liumen, 1930, p. 490); locomotives were all steam driven (Yang Yi, 1948, pp. 1–4); and the vast majority of domestically built inner-river or

ocean-going ships were still steam propelled (Wang Shiquan, 1948 pp. 2–3).

Stone Beads

Daniella Bar-Yosef Mayer

Tel Aviv University, Tel Aviv, Israel

Harvard University, Cambridge, MA, USA

Beads are small artifacts, usually perforated, that are used for adornment on the human body, clothes, artifacts, or animals. They are used to express social status, wealth, gender, and other symbolic attributes. The earliest known prehistoric beads were made of seashells (from about 100,000 years ago). From about 50,000 years ago, ostrich eggshell, animal bone and teeth, ivory, and antler were also used (Taborin 2004; Álvarez Fernández and Jöris 2008; Miller and Willoughby 2014). The earliest stone beads found in Upper Paleolithic sites in Western Europe from ca. 32 ka were made of mostly clay and soft stones (chlorite, talc, calcite, hematite, and lignite; Taborin 2004; White 2007). The earliest known wooden beads are Neolithic (Nahal Hemar Cave, Israel; Werker 1988). Metal beads were first made of copper (in ninth millennium BCE Anatolia) and are later made of gold and silver. The crushing, shaping, and heating of soapstone into a paste which became glazed enstatite in the fifth millennium BC in Pakistan form another leap forward, which lead to the production of faience, then glass

beads in the third millennium BCE in Egypt and the Near East (Lankton 2003; Bar-Yosef Mayer et al. 2004; Dubin 2009). Additionally seeds and other organic materials served as beads.

Stone beads become widespread around 12,000 years ago, for example, when amber beads appear in Starr Carr, England, jade beads appear in Japan in Early Jomon sites, and apatite and other green mineral beads and pendants appear in the Levant in the Late Natufian culture. Besides their role of adornment and symbolism, they become a trade and exchange item in a society that changed its economic basis from hunting and gathering to farming and herding (Bar-Yosef Mayer 2013; Wright and Garrard 2003).

Hundreds of rocks and minerals exist in nature, but only a selection, which are relatively easy to find and durable enough, were chosen for bead production. Stone beads are made of either minerals, composed of a specific combination of elements (e.g., quartz, a combination of silica and oxygen, SiO₂), or rocks made of a combination of minerals, but are sometimes monomineralic (Table 1). Their proper identification may indicate the origins of the raw material, vital to archaeological research (Rapp 2002; Aston et al. 2000). Lab tests used for materials identification include hardness (Mohs scale); the presence of carbonates using hydrochloric acid; structure as seen under a stereoscopic microscope; mineralogical composition using one of more of the following methods, Scanning Electron Microscope equipped with Energy Dispersive Spectroscopy (SEM-EDS), X-ray fluorescence (XRF), X-ray diffraction (XRD), and Fourier transform infrared spectroscopy (FTIR); and isotopic composition. For example, limestone and calcite beads can be divided using XRF, but to differentiate them from shell disk beads, one should use a microscope that will reveal their structure, and in order to differentiate them from marble, ratios of oxygen isotope should be tested for.

Stone beads research is based mostly on typology and technology that indicate the period and culture that beads were made in. Typology was first developed by Horace Beck but each region

Stone Beads, Table 1 Common stone types used to produce beads

Category	Group/class/family	Name	Other names or minerals
Rock	Igneous	Basalt	
		Obsidian	
	Sedimentary	Limestone	Calcareneite
		Sandstone	
	Metamorphic	Marble	
		Quartzite	
		Steatite	Soapstone, talc
		Jade	Nephrite, jadeite
		Serpentine	Serpentine
Mineral	Carbonates	Calcite	
		Malachite	
	Phosphates	Apatite	
		Fluorapatite	
		Turquoise	
	Silica (SiO ₂)	Quartz	Rock crystal
		Amethyst	
		Agate	
		Cornelian	
		Onyx	
		Jasper	
	Aluminum silicates	Garnet	Lapis lazuli
		Amazonite	
		Lazurite	
		Chlorite	
	Sulfate	Gypsum	
	Iron oxides	Ochre	
		Hematite	
Fossilized tree resin		Amber	

and period require specific definitions (Beck 1928; Bar-Yosef Mayer 2013). Technological traditions are continuous in some regions for many millennia (e.g., the Indus Valley), and recent ethnographic observations shed light on past activities (Kenoyer 1991; Kenoyer et al. 1991; Roux 2000; Caubet 1999). The indistinct shapes of rocks and minerals require planning ahead for the artifact produced. It involves the collection of raw materials, hammering and sawing into a rough shape, fine chipping and grinding into a bead blank, drilling, filing, or polishing sometimes complemented by etching. Heating (especially cornelian) enhances the color and if practiced it is a first step before shaping.

In the case of thin disk beads, the perforation precedes filing, and then a group of beads strung together is filed to produce beads of equal diameter. Perforation methods include the use of a hand, bow, or pump drill, with drill bits made of flint or harder materials. In later periods metal drills were used, and abrasive materials added (Kenoyer et al. 1991; Gwinnett and Gorelick 1999; Roux 2000; Lankton 2003).

Beads have universal symbolic meanings based on their colors or shapes. Red universally connotes the color of blood, which life depends on and in ancient Egypt it symbolized energy, dynamism, and power. It also embodies blood of sacrifice or resulting from violence. Red or reddish beads were made in the old world first from ochre and clay, then from carnelian. In South America red shells and corals were used for the same purpose. Cornelian was common in the civilizations of Egypt, Mesopotamia, and Indus valley but is also known from East Africa. In the nineteenth century, cornelian from Brazil was imported to Germany where it was made into beads that were traded to Africa. Red, white, and black beads are among the oldest. White is often associated with purity and perhaps innocence as it relates to human milk and semen, and as an example, among Bedouin women, white beads serve to enhance the milk of a mother. Black is associated with excreta and earth and denotes decay, but in ancient Egypt, it is considered to represent depth and profundity (Andrews 1994; Sciamia and Eicher 1998; Morris and Preston-Whyte 1994; Mershen 1989; Kay and McDaniel 1978).

Ethnographically green and blue indicate ripeness, fertility, and strength. In ancient Egypt, it is the color of new vegetation and symbolic of new life. It has been suggested that the appearance of green beads during the agricultural revolution was as fertility charms and as amulets to ward off the evil eye (Bar-Yosef Mayer and Porat 2008). Green and blue beads, made of copper bearing minerals (malachite, chrysocolla) but also turquoise and lapis lazuli, are associated with growth, productivity, and good health. They can be found in Mesopotamia and ancient Egypt, as well as Mesoamerica and South America and the American Southwest. Jade beads and

pendants are known from East Asia, mostly China, as well as ancient Mesoamerica but also from Maori New Zealand. Turquoise was mined in Southwest USA (Chaco Canyon in New Mexico being the most famous) and traded into Mexico. Turquoise was also mined in the past in Persia and Sinai, from where it was transported to ancient Egypt (Andrews 1994; Hull et al. 2014; Tait 1986).

Neither rock nor mineral, amber is known mostly from the Baltic region from where it was traded to western Asia in the third millennium BC and in historic period to East Africa and Arabia. In some Bedouin societies, yellow beads often made of amber are apotropaic against jaundice. Brown and purple are less fundamental colors and are more rare in the ethnographic and archaeological record of beads and ornaments (Mershen 1989; Dubin 2009).

Gemstones, not perforated but cut and inlaid in metal, are broadly associated with nobility, examples being the Turkish sultans and their contemporaneous Mughal dynasty of India. The precious stones ruby and sapphire (two forms of corundum), emerald, and diamond are extremely hard and usually not exposed on the surface of the earth; therefore they were rare in antiquity. Rubies are known from China from about 200 BC and in the past were used as drills for making beads of softer stones, as were diamonds in India (Tait 1986).

Beadwork, the union of a group of beads with or without thread into one artifact such as an apron or necklace, is first found with stone beads from Egypt in the late third millennium BCE. In beadwork, stone beads are sometimes combined with beads of other raw materials (Hector 2005). One type of beadwork is prayer beads used to count prayers that originated in India in the second century BCE and which are common in Hindu, Buddhist, Islamic, and Catholic rosaries (Tait 1986; Dubin 2009). Based on observations of hundreds of photos and items in museums, it appears that most non-western cultures today use mostly colored glass seed beads, shell, and metal with relatively small numbers of stone beads (Allen and Hector 2007).

Stone in Ancient Egypt

James A. Harrell

University of Toledo, Toledo, OH, USA

Rock Varieties and Sources

Much of what remains of ancient Egypt consists of stone (Aston, Harrell, & Shaw, 2000; Baines, 2000; De Putter & Karlshausen, 1992; Klemm & Klemm, 2001, 2008). There are building stones for temples, pyramids, and tombs; ornamental stones for vessels, sarcophagi, shrines, stelae, statues, and other sculptures; gemstones for jewelry; and utilitarian stones for tools, weapons, pigments, and other applications. Still other stones were processed to extract their precious metals. This record of stone use ranges from the

Stone in Ancient Egypt, Table 1 Ancient Egyptian chronology

Predynastic or Neolithic period (5500–3100 BCE)
Dynastic or Pharaonic period (3100–332 BCE): dynasties 1–30
Early dynastic period (3100–2686 BCE): dynasties 1 and 2
Old kingdom (2686–2160 BCE): dynasties 3–8
First intermediate period (2160–2055 BCE): dynasties 9 to early 11
Middle kingdom (2055–1650 BCE): dynasties late 11–14
Second intermediate period (1650–1550 BCE): dynasties 15–17
New kingdom (1550–1069 BCE): dynasties 18–20
Third intermediate period (1069–664 BCE): dynasties 21–25
Late period (664–332 BCE): dynasties 26–30
Greco-Roman period (332 BCE–395 CE)
Ptolemaic period (332–30 BCE)
Roman period (30 BCE–395 CE)

Predynastic period (beginning about 5500 BCE) to the Roman period (ending about 400 CE; Table 1). In common parlance, the term “stone” includes “rocks” as well as the “minerals” they contain. There are three general categories of rocks – sedimentary, igneous, and metamorphic – and these are further subdivided according to their textures and constituent minerals.

Sediments (mud, sand, and gravel) deposited on ocean floors and land surfaces are hardened into sedimentary rocks through a variety of lithification processes, including compaction, cementation, and recrystallization. Continental sediments are derived from weathered and eroded preexisting rocks and are deposited mainly by rivers but also occasionally by wind, glaciers, and other processes. Marine sediments, in contrast, are composed mainly of biogenic material (hard skeletal parts of algae, protozoa, and especially invertebrate animals) or inorganic precipitates produced by evaporation of seawater, but also sometimes include continental sediments carried by rivers to the seas. Other sedimentary rocks are the result of secondary mineralization of preexisting sedimentary rocks.

Sedimentary rocks used by the ancient Egyptians include limestone (from biogenic marine sediments); rock gypsum and rock anhydrite (both from evaporative marine sediments); sandstone, including the harder silicified (quartz-cemented) sandstone or quartzite (from continental sediments and, in part, shallow nearshore marine sediments); and travertine and chert (both from secondary mineralization of limestone). Nearly all the ancient quarries for limestone, travertine, and chert were located in the hills and cliffs bordering the Nile River valley between Cairo in the north and Isna in the south. Some limestone was also quarried along the Nile Delta’s Mediterranean coast near Alexandria. Quarries in the Nile valley from Isna southward into northern Sudan supplied the sandstone. Silicified sandstone came only from the Aswan area and Gebel Ahmar near Cairo. Rock gypsum and rock anhydrite were obtained from Egypt’s Red Sea coast, and rock gypsum also came from the Faiyum in the Western Desert. A beautiful blue rock anhydrite has no known Egyptian source and so may have been imported.

Igneous rocks form through the crystallization of magma (molten rock). They are referred to as “plutonic intrusives” when they form deep below the Earth’s surface, “volcanic intrusives” when emplaced in the shallow subsurface (dikes and related rock bodies), and “volcanic extrusives” when coming from a volcano and deposited on the surface (lava flows, and airborne pyroclastic falls and flows).

Igneous rocks used by the ancient Egyptians include granite, granodiorite, pegmatitic diorite, peridotite, and quartz diorite (plutonic intrusives); andesite, dacite, dolerite, rhyolite, and trachyandesite porphyries (volcanic dikes and lava flows); basalt and obsidian (volcanic lava flows); and tuff (volcanic pyroclastics). Apart from the famous granite and granodiorite quarried at Aswan on the Nile River and another variety of granite further up the Nile at northern Sudan’s Third Cataract, the igneous rocks came from the Faiyum in the Western Desert (basalt) and especially the mountains of the Eastern Desert (all other rocks, excluding obsidian). Obsidian (volcanic glass) does not occur in

Egypt and was imported either from the eastern Mediterranean or southern Red Sea regions.

Metamorphic rocks are derived from preexisting sedimentary, igneous, or other metamorphic rocks through the application of high pressures, high temperatures, or chemically active hydrothermal fluids deep below the Earth's surface. The metamorphosis occurs in the solid state (without melting) through secondary mineralization and recrystallization. The resulting rocks are either foliated, with a parallel alignment or planar segregation of their constituent minerals, or non-foliated.

Metamorphic rocks used by the ancient Egyptians include anorthosite, gabbro, granite, granodiorite, and tonalite gneisses (foliated) and marble, metaconglomerate, metagabbro, metagraywacke, serpentinite, and steatite (non-foliated). The anorthosite and gabbro gneisses come from the Nubian Desert west of Lake Nasser, the granite and granodiorite gneisses were taken from the Third and Fourth Nile Cataracts in northern Sudan, and all the other rocks were quarried in the mountains of the Eastern Desert.

The other stones employed by the ancient Egyptians are minerals found mostly within the plutonic and metamorphic rocks. These are the gemstones used for jewelry and include amazonite, a variety of microcline feldspar; emerald, a variety of beryl; fluorite; garnet; hematite; jade (or nephrite); Libyan desert glass; malachite; macrocrystalline quartz (amethyst, milky quartz, and rock crystal), microcrystalline quartz (banded agate, bluish-white chalcedony, carnelian, jasper, onyx, petrified wood, sard and sardonyx); peridot, a variety of olivine; turquoise; and occasionally other stones. These minerals were mined in the Sinai (turquoise), St John's (or Zabargad) Island in the Red Sea (peridot), the Nubian Desert west of Lake Nasser (agate, carnelian, and other chalcedonies), the sand sea in the Western Desert (Libyan desert glass), and the mountains of the Eastern Desert (all the rest). Lapis lazuli, a gemstone rock rather than a mineral, was also widely used in Egypt but was apparently imported from Afghanistan. During the Ptolemaic and Roman periods, other

gemstones were imported from India, including aquamarine (a variety of beryl), garnet, onyx, sapphire (a variety of corundum), and sardonyx. The plutonic igneous and metamorphic rocks are also the source of much of ancient Egypt's gold, copper, silver, tin, and some iron and lead, with sedimentary rocks supplying additional copper, iron, and lead. All of these were obtained from the Eastern Desert with much of the copper (derived mainly from malachite and chrysocolla) also coming from the Sinai.

Plate tectonics and other earth movements in combination with erosion processes have brought the originally deeply buried sedimentary, igneous, and metamorphic rocks to the surface in Egypt. The geologic map in Fig. 1 shows the generalized distribution of these rocks. The exposed plutonic igneous and metamorphic rocks, which form mountains in the Eastern Desert, are commonly referred to as the Precambrian "crystalline basement" and in Egypt are over 550 Ma old, whereas the sedimentary and volcanic igneous rocks are mostly less than 100 Ma in age. For images of many of the stones used by the Egyptians as well as information on the ancient mines and quarries, see Harrell (2012a, 2012b, 2012c, 2012d) and Harrell and Storemyr (2009).

Building Stones

Limestone and sandstone were the main building stones of ancient Egypt. From Early Dynastic times onward, limestone was the material of choice for pyramids, mastaba tombs, and temples within the limestone region. From the late Middle Kingdom onward, sandstone was used for temples within the sandstone region as well as many of those in the southern part of the limestone region. Both limestone and sandstone were also employed for statuary and other non-architectural applications, when harder and more attractive ornamental stones were not available. Along the Red Sea coast, the temples and other important buildings of the Ptolemaic and Roman periods were built with the locally available rock gypsum and rock anhydrite.

Stone in Ancient Egypt, Fig. 1 Generalized geologic map of Egypt (Adapted from an unpublished geologic map by the Egyptian Geological Survey and Mining Authority)

Ornamental Stones

In contrast to the drab, unpolished building stones, those employed for ornamental applications have attractive colors and patterns and also take a good polish due to their greater hardness. The principal applications of the various stones and their periods of use are as follows:

1. Exterior veneer on pyramids: Old Kingdom – granite and granodiorite.
2. Pyramid capstones: Old and Middle Kingdoms – granodiorite and possibly basalt.
3. Linings of burial chambers and passages in pyramids and mastaba tombs: Early Dynastic period through Middle Kingdom – granite, granodiorite, and silicified sandstone.

4. Door lintels, jambs, and thresholds of temples: Early Dynastic through Roman periods – granite, granodiorite, and silicified sandstone.
5. Temple pavements: Old Kingdom – basalt, bituminous limestone, and travertine.
6. Temple columns: Old and Middle Kingdoms – granite.
7. Temple walls: Old Kingdom – basalt, bituminous limestone, granite, and granodiorite.
8. Interior wall veneer, pavement, columns, and other architectural elements for temples and other buildings: Ptolemaic period – granodiorite; Roman period – andesite-dacite porphyry, granite, granodiorite, metaconglomerate, metagabbro, metagraywacke, pegmatitic diorite, quartz diorite, rhyolite porphyry, tonalite gneiss, and trachyandesite porphyry.
9. Basins: Roman period – andesite-dacite porphyry, granite, and tonalite gneiss.
10. Barque shrines: Middle and New Kingdoms – granite, silicified sandstone, and travertine.
11. Small statue shrines (naoi): Old Kingdom through Roman period – granite, granodiorite, metagraywacke, and silicified sandstone; Middle Kingdom – travertine; Late Period – dolerite porphyry; Roman period – metagraywacke.
12. Obelisks: New Kingdom – granite, metagraywacke, and silicified sandstone; Roman period – granite.
13. Offering tables: Old Kingdom through Roman period – granite, granodiorite, metagraywacke, silicified sandstone, and travertine.
14. Small vessels and figurines: Predynastic period through Old Kingdom – andesite porphyry, anorthosite gneiss, basalt, bituminous and buff limestones, dolostone, gabbro gneiss, granite, metaconglomerate, metagraywacke, obsidian, pegmatitic diorite, quartz rock crystal, red-and-white limestone breccia, rock gypsum, serpentinite, silicified (petrified) wood, travertine (the most commonly used stone), tuff, and tuffaceous limestone; Early Dynastic period and Old Kingdom – recrystallized limestone; Middle Kingdom and Second Intermediate period, blue rock anhydrite.
15. Canopic jars (placed in tombs for storage of the decedent's viscera): Old Kingdom through Roman period – travertine.
16. Sarcophagi: Old through New Kingdoms – travertine – Old Kingdom and Late to Ptolemaic periods – basalt; Old Kingdom through Roman period – granite, granodiorite, metagraywacke, and silicified sandstone; New Kingdom through Late Period – metaconglomerate.
17. Sarcophagus plinths: New Kingdom – travertine.
18. Embalming tables: Late Period – travertine.
19. Small to colossal statues and other sculptures: Early Dynastic through Roman periods – granite, granodiorite, metagraywacke, red-and-white limestone breccia, silicified sandstone, and travertine; Old and Middle Kingdoms – anorthosite gneiss and gabbro gneiss; Old through New Kingdoms – buff limestone; New Kingdom – marble and peridotite; New Kingdom through Roman period – granite gneiss and granodiorite gneiss; Late Period – dolerite porphyry; Late through Roman periods – basalt and metaconglomerate; Roman period – andesite-dacite porphyry.
20. Scarab and shabti (a model servant figure placed in tombs to assist the decedents) figures: New Kingdom through Roman period – metagraywacke, serpentinite, steatite (usually glazed), and travertine.
21. Stelae: Old Kingdom through Roman period – granite – granodiorite, metagraywacke, and silicified sandstone; Late Period – granite gneiss, granodiorite gneiss, and metaconglomerate.
22. Cosmetic and ceremonial palettes: Predynastic and Early Dynastic periods – metagraywacke.
23. Headrests: Old through New Kingdoms – travertine.
24. Ceremonial mace heads: Predynastic and Early Dynastic periods – andesite porphyry, granite, granodiorite, red-and-white limestone breccia, metagraywacke, pegmatitic

diorite, recrystallized limestone, travertine, and occasionally other stones.

Note that many of the above objects were also carved from non-ornamental limestone and sandstone.

Gemstones

The many precious and semiprecious gemstones available to the ancient Egyptians were employed primarily for beads, pendants, amulets, inlays, and seals. The periods of use for the many gemstone varieties are as follows: Predynastic period – fluorite; Predynastic period through Middle Kingdom – milky quartz; Predynastic period through New Kingdom – malachite; Predynastic through Roman periods – amazonite, banded agate, bluish-white chalcedony, carnelian (and sard), garnet, hematite, jasper, lapis lazuli, onyx, sardonyx, steatite (usually glazed), and turquoise; Middle Kingdom and Ptolemaic and Roman periods (and very rarely at other times) – amethyst; New Kingdom – jade, Libyan desert glass, and petrified wood; Ptolemaic and Roman periods – peridot; and Roman period – aquamarine, emerald, and sapphire.

Utilitarian Stones

Perhaps, the heaviest used and least glamorous stone employed by the ancient Egyptians is chert, which is also commonly referred to as flint. From Predynastic times onward, it was used for tools (adzes, knives, and sickle blades; ax and pick heads; choppers; drill bits; and scrapers) and weapons (dagger blades and spear and arrow points). Even when metals (copper, bronze, and later iron) became commonplace for these applications, chert was still a popular low-cost alternative. For tools and weapons requiring the sharpest edges, imported obsidian was employed. A wide variety of stones, especially hard ornamental ones, were used for the heads of maces, a club-like weapon.

From Predynastic times into the Late Period, the quarrying and much of the carving of ornamental stones was done with hard, fracture-resistant stone tools known as pounders and mauls. These were primarily of dolerite, but silicified sandstone, anorthosite gneiss, and fine-grained granite were also occasionally used. These same rocks, especially silicified sandstone, were additionally employed as rubbing stones for smoothing rough stone surfaces. The actual polishing of these surfaces was probably done with ordinary, quartz-rich sand of which Egypt abounds. For quarrying the softer sandstone and limestone, metal chisels struck by wood mallets were employed. The metal was originally copper and this was gradually replaced by the harder bronze during the Middle Kingdom, and by the Late Period, tools of the still harder iron came into use.

Eye shadow made from finely ground galena (dark gray) and malachite (green) was used by both Egyptian men and women. The grinding was done on cosmetic palettes carved mainly from metagraywacke. Egyptian temples and tombs were richly painted with bright primary colors made largely from ground stones: azurite (blue), gypsum and limestone (white), hematite ochre (red and orange), limonite ochre (yellow and brown), and malachite (green).

Grinding stones for grain have been used throughout Egyptian history, and generally were carved from the harder and less valuable ornamental stones, such as granite, granodiorite, and silicified sandstone. During the Ptolemaic and Roman periods, large numbers of grinding stones made from vesicular basalt were imported.

Extra 1: What Is in a Name?

A persistent problem in Egyptian archaeology is the misidentification of ornamental stones. The primary sources of these errors are archaeologists, museum curators, and art historians who are unfamiliar with correct petrological nomenclature as applied by geologists. Geologists themselves have also contributed to the problem by applying different, competing rock classifications

to the stones. It is not uncommon to see objects carved from the same stone referred to by multiple, contradictory rock names in museum exhibits and catalogs as well as in reference works. This is not only a great source of confusion to the general public, but it has also misled some scholars into thinking the different rock names refer to different materials. A classic example of this problem is the stone known by the technically correct name “metagraywacke” (a slightly metamorphosed graywacke sandstone to siltstone), which is commonly referred to incorrectly as schist, slate, basalt, and siltstone. Travertine is another notorious example. This stone, which consists of the mineral calcite, is frequently called alabaster, which in geological nomenclature is a rock consisting of the mineral gypsum. In an effort to avoid this misidentification, travertine is increasingly being referred to as “calcite-alabaster” or simply “calcite.”

Another commonly misidentified stone is the granodiorite from Aswan, which is often referred to as black granite, diorite, or basalt. For example, the famous Rosetta Stone, which provided the key to translating Egyptian hieroglyphic writing, is widely described as basalt when it is actually Aswan granodiorite. A final example is the anorthosite gneiss from the Nubian Desert, which is frequently misidentified as diorite.

Extra 2: Bekhen-Stone to Basalt

Basalt is the fine-grained, black volcanic rock seen in lava flows all over the world. What few realize is that the word *basalt* is of ancient Egyptian origin. It began in the third millennium BCE as *bekhen*, which was the ancient name for a dark grayish green metagraywacke, a slightly metamorphosed graywacke sandstone to siltstone, quarried in Egypt’s Wadi Hammamat. During the Greco-Roman period, *bekhen* was transliterated into *basanites*, and during the Middle Ages, a transcription error in a copy of Pliny the Elder’s *Natural History* changed *basanites* to *basaltes*. This error went undetected in subsequent centuries when Pliny’s description of the misnamed

basaltes as having a “dark color and hardness of iron” was mistakenly thought to refer to the volcanic rock that today we call *basalt*.

Extra 3: Limestone or Concrete Pyramids?

The Old Kingdom pyramids at Giza, Saqqara, and other nearby necropoli on the Nile River’s west bank have long been recognized by Egyptologists and geologists as having been constructed with blocks of limestone. The limestone for the bulk of the pyramids, the core blocks, came from quarries excavated in the limestone bedrock surrounding the pyramids. A better-quality limestone, with a uniform light gray color and finer texture, was applied over the core blocks to form the pyramids’ exterior surfaces. These casing blocks came from the Tura-Masara quarries across the Nile River, on its east bank.

In the early 1990s, these long-held beliefs about the building materials for the pyramids were challenged by David Davidovits, a French materials scientist, who claimed the pyramids were made from poured concrete rather than quarried limestone. Although the concrete pyramids hypothesis has received a lot of attention in the international media, Davidovits has so far failed to convince any Egyptologists or geologists of his views. The reasons for this are two-fold. First, Davidovits’ arguments ignore and run counter to nearly all archaeological and geological evidence bearing on the pyramids. And second, Davidovits has been unable to experimentally produce a concrete resembling the pyramid stones using the techniques he thinks the ancient Egyptians employed.

The Importance of Arabia in Prehistory

Prehistoric research in the Arabian Peninsula is in its infancy, and it has long been treated as an

empty spot on the archaeological world map. While information about Arabian prehistory is still relatively scarce, archaeological sites are, in fact, abundant. Archaeological sites are found in many places across Arabia, usually represented by stone tool industries. Arabia is a key geographic zone of the Old World, as it lies at the crossroads of three continents: Africa, Europe, and Asia. The Peninsula therefore plays a leading role for studying the worldwide expansion of early humans.

Archaeological surveys have been carried out in Arabia for more than half a century, revealing the existence of prehistoric sites spanning over a long time period, some perhaps extending back to more than one million years ago. Stone tools (also called lithics) represent the main kind of material objects found in archaeological sites. Based on the typology of stone tools, archaeologists working in Arabia have constructed a chronological and cultural framework that was modeled after the technological stages known elsewhere, such as the Lower Paleolithic (Oldowan, Acheulean) and the Middle Paleolithic (sometimes labeled as Mousterian or Middle Stone Age). All archaeological site discoveries made in Arabia were adapted to this broad typological and chronological framework. Prehistoric research in Arabia is currently progressing, as Paleolithic sites have now been radiometrically dated and systematic site excavations have been conducted.

Having today a somewhat better picture of the chronological framework of prehistoric Arabia, lithic industries are currently being compared with better-established neighboring stone tool assemblages, such as those of northeast Africa and the Levant. Comparisons are important in this case, as there is a desire to determine the regional source of Arabian populations. Stone tool industries in Arabia can therefore provide an opportunity to examine cultural influences and interconnections and human migrations and dispersals.

Paleoenvironmental research has been growing in Arabia over the past few years, situating prehistoric activities in ecological context. Studies include study of satellite images to identify

paleohydrological features (lakes, rivers), analysis of riverine and lacustrine (lake) deposits themselves, and study of cave speleothems which provide an accurate picture of climate change history. All of these studies contribute to the reconstruction of past environmental conditions, providing a framework to understand prehistoric occupations and activity.

The Peopling of Arabia

The oldest archaeological sites identified in Arabia are not well dated, but based on interregional analysis and stone tool typology, they comfortably belong to a Lower Paleolithic tradition known as the Acheulean, dated between 1.7

million years ago and 200,000 years ago. Lithic industries typed as Acheulean typically contain large bifacially made artifacts, called handaxes and cleavers, as well as simpler tools, called choppers. These large bifacial tool forms are hand-held implements, probably used in a variety of tasks, such as butchering animal carcasses.

Middle Paleolithic stone tool industries are better known in Arabia in comparison to Lower Paleolithic industries (Fig. 1). In Europe, the Levant and Africa, the Middle Paleolithic is generally characterized by Levallois flaking methods, which begins in the late phases of the Acheulean. Levallois technology is characterized by a hierarchical system of flaking, including predetermined forms of flaking products. Middle

Stone Technology in Arabia, Fig. 1 Arabian Paleolithic stone technology: (1) Lower Paleolithic Acheulean handaxe (From Jubbah, JKF-8 site, northern Saudi Arabia); (2) Middle Paleolithic (MP) Levallois preferential core (From Jubbah, JSM-1 site); (3) MP Levallois

preferential flake (From Jubbah, JKF-1 site); (4) MP retouched tool (From Mundafan, MDF-1 site, southern Saudi Arabia); (5) MP Levallois preferential core (From Al-Kharj, AK-22 site, central Saudi Arabia); (6) MP Nubian core (From Al-Kharj, AK-22 site)

Paleolithic industries in Arabia are also characterized by Levallois tool methods. The key innovation is the use of flakes for tipping spears, thus providing advantages to prehistoric hunters who were able to kill prey from a distance more efficiently.

Middle Paleolithic sites are found all across the Arabian Peninsula, thanks to numerous surveys by archaeologists. In recent years, archaeologists have identified sites with stone tools in stratigraphic context and in association with absolute dates ranging between 125,000 and 55,000 years ago. The main sites are Jebel Faya (Marine Isotopic Stage (MIS) 5e, United Arab Emirates; Armitage et al., 2011), the Nubian Complex of Arabia (MIS 5c, South and Central Arabia; Crassard & Hilbert, 2013; Rose et al., 2011), the Jubbah paleolake localities (MIS 7 to MIS 5c, northern Saudi Arabia; Petraglia et al., 2012), the Mundafan paleolake localities (MIS 5, southern Saudi Arabia; Crassard et al., 2013), and Wadi Surdud (MIS 3, southwestern Yemen; Delagnes et al., 2012). The episodic peopling of Arabia during the Middle Paleolithic is associated with well-established humid phases in which increased rainfall facilitated the expansion of both freshwater systems and mammal populations (Groucutt & Petraglia, 2012). Conversely, during arid or hyper-arid periods, the Arabian environment may have presented a substantial obstacle to human survival, at times resulting in population contraction into refugium zones [areas of relatively unaltered climate that are inhabited by plants and animals during a period of continental climatic change]. The Nubian sites in south and central Arabia were only formerly known in southern Egypt and northern Sudan; hence recovery of them raises questions as to whether these tool industries represent an early expansion out of Africa by our species *Homo sapiens*).

The Late Prehistory of Arabia

Stone tool industries dating to 50,000 years ago and later are characterized by the use of blade technology. Blade tool industries, called Upper

Paleolithic in the Levant and Europe and Late Stone Age in Africa, are still extremely rare in the Arabian Peninsula. The absence of these blade industries in Arabia raises the question as why the Peninsula was uninhabited during this period. Alternatively, the absence of these industries in Arabia may, in part, be due to preservation conditions, or perhaps a product of the lack of research. Though rare, recent discoveries in southern Oman could help to fill the gap in our knowledge about such sites, as blade tool assemblages have been found that may date back to 20,000 years ago (Hilbert, 2014). From the information available today, it is also possible to suggest that some regions of Arabia were sparsely inhabited, explaining the paucity of Upper Paleolithic sites, whereas in other more favorable ecological settings, foraging populations may have been continually present.

During the Early Holocene, after 10,000 years ago, stone tool assemblages begin to include projectile weaponry (Fig. 2). Stone tools include small tanged arrowheads made on a thin flake or blade-like blanks. Certain forms of arrowheads, named Fasad points, appear to be geographically restricted to the southern part of the Peninsula, especially in Oman and the Emirates (Charpentier & Crassard, 2013). Later on, and in correspondence with the rise of the Neolithic (mainly characterized by pastoralism) from the mid-seventh millennium BC, a typical facies of trihedral arrowheads appears in Yemen and spreads across southern Arabia, from the Red Sea coast to the Gulf. These finely made trihedral arrowheads are bifacially, and sometimes trifacially, shaped, showing a triangular cross section. Some of these stone tool forms are fluted, the fluting method consisting of the extraction of a flake along the longitudinal axis of the point, on its ventral face. This highly characteristic fluting method of stone tool manufacture is so far only found in south Arabia. Neolithic developments include the production of sophisticated bifacial foliate industries and other types of bifacial and unifacial arrowheads, as well as small finely shaped semicircular end scrapers (Crassard & Drechsler 2013),

Stone Technology in Arabia, Fig. 2 Arabian Late Prehistory stone technology: (1–3) El-Khiam and Helwan points (From Jubba, JQ-101 site, northern Saudi Arabia); (4) Fasad point (from Qi Haid site, Oman); (5) Trihedral point (From Manayzah site, Yemen); (6) Trihedral point

(From HDOR-419 site, Yemen); (7–8). Fluted points (From Manayzah site, Yemen); (9–11). Bifacial arrowheads and tool (From Mundafan, MDF-16 and MDF-20 sites, southern Saudi Arabia)

quite clearly present in the whole of south Arabia. For the rest of the Peninsula, stratified and dated Early and Mid-Holocene sites are still infrequent. Surface finds (sometimes broadly attributed to a vague “Arabian Bifacial Tradition”) indicate a probable difference with the traditions observed in Yemen, Oman, and the Gulf.

Stone technology does not entirely disappear in the Bronze Age which begins at about the fourth millennium BC. Yet, there is a clear tendency for expediency: retouched tools are made on flakes, with no particular method to produce specific forms of particular sizes and shapes. The blade and bladelet component, sometimes abundant in Neolithic assemblages, begins to disappear in favor of metal products. During the Bronze Age and Iron Age in Yemen, geometric microlith traditions are reinvented. These tool forms are typically made of a distinctive volcanic material called obsidian, found locally and imported from Africa. These microlithic tool forms represent the final phase of stone tool industries used in Arabia, coming to an end by the beginning of the Common Era (Crassard, 2008).

Conclusions

Arabia is central in debates concerning human origins and the colonization of the Old World. Stone technology helps archaeologists to examine cultural traditions, human activities, and population relationships and movements. Today’s explorations and excavations are helping to improve our understanding of Arabia’s role in past history, and studies of stone technology are fundamental in tracing interactions, influences, and dispersals of early human groups out of, and into, Africa. Analysis of stone tool variations and patterns also help in evaluating the more recent peopling and re-peopling of the Arabian Peninsula, up to the rise of urbanized and complex civilizations.

Stone Tools in Mesoamerica: Flaked Stone Tools

Bradford W. Andrews

Department of Anthropology, Pacific Lutheran University, Tacoma, WA, USA

Flaked stone tools in pre-Hispanic Mesoamerica were used for a wide range of domestic, militaristic, and ritualistic activities. Geographically, Mesoamerica refers to present-day Mexico, Guatemala, Belize, and parts of Honduras and El Salvador. The prismatic blade was the most common tool, usually made of obsidian, which was the most important tool stone in the region (see “[Extra: Obsidian in Mesoamerica](#)”). Flake tools and biface implements, like projectile points and knives, were also used throughout Mesoamerica. These implements, however, were not as prevalent as blade tools except during early Mesoamerican prehistory or at sites like Colha in the chert-bearing zone of Belize where obsidian was scarce (Fig. 1) (Hester & Shafer, 1994; Shafer & Hester,

1983). This discussion focuses on the Mesoamerican blade technology, but flake and biface technologies are also reviewed. Reference is made to chronological trends and how blades and other items were produced and used. Although the topic here is technological, obsidian production and use also had considerable symbolic and ritual significance (see “[Extra: The Ideological Significance of Obsidian](#)”).

Early Prehistory

Research indicates that as early as 15000 BCE, small foraging groups who made impressive projectile points inhabited much of Mesoamerica (MacNeish, 1976; Weaver, 1981). These groups are referred to as Paleo-Indian (prior to 7200 BCE) “big-game” hunters. They practiced a biface technology requiring the use of percussion and pressure techniques to shape biface (e.g., projectile points) and uniface (scrapers) tools. The manufacture of biface tools like projectile points requires the removal of flakes from both sides or “faces” of a relatively flat piece of stone.

Stone Tools in Mesoamerica: Flaked Stone Tools, Fig. 1 Map of Greater Mesoamerica (Illustration by the author)

Stone Tools in Mesoamerica:

Flaked Stone Tools,

Fig. 2 The direct freehand percussion technique (Illustration by Karen Andrews. Used with her permission)

Uniface tools like many scrapers, in contrast, are made by removing flakes from only one side of a piece of stone. The flaking techniques used to make both types of implements are similar, so they are referred to here as products of biface technology.

Paleo-Indian bifaces were initially made from large flakes using direct percussion, which were then “thinned” with pressure. Direct percussion involved directly striking a piece of raw material (i.e., nodule, flake, or blade) with a stone, bone, antler, or wood hammer (Fig. 2) (Hester, 1972, p. 99). In contrast, the pressure technique involves placing a tool of bone, antler, or wood against the edge of a piece of raw material and pushing on it to “press” off flakes.

Many Paleo-Indian points in Mesoamerica were the fluted varieties associated with the Clovis and Folsom Traditions (Weaver, 1981). Clovis points have been found in Northern and Western Mexico and as far south as El Salvador (Weaver, 1981). In Central Mexico, a similar development referred to as the Cordilleran Tradition emerged around 13000 BCE; it was associated with the appearance of pressure flaked, willow-shaped projectile points, crude blades, and scrapers (MacNeish, 1976, p. 322, Fig. 2). Early Paleo-Indian points were hafted on spears and used as thrusting weapons. By about 9000 BCE, however, the *atlatl* or spear thrower appeared, providing hunters with greater thrusting force and accuracy. In the Aztec language of Nahuatl, the word *atlatl* refers to what is known in English as the spear thrower. This device consists

of a stick that supports a dart-tipped shaft. During the throwing action, the stick acts as an extension of the arm and a lever that propels the “butt” end of the dart shaft generating greater thrusting power and accuracy than a shaft thrown by hand (Adams, 1977, p. 339). Point size is usually used to differentiate larger spear points from smaller *atlatl* points, with *atlatl* points measuring generally less than 6 or 7 cm in length. This criteria is subjective, however, and many finely flaked points dating to this period could have been either spear or *atlatl* points (Fig. 3).

The appearance of the spear thrower occurred in tandem with the gradual replacement of big-game hunters by groups who foraged for a wider range of plant and animal resources. This shift is associated with the Mesoamerican Archaic period (7200–2500 BCE). Generally, Archaic flaked stone tools are characterized as expedient, consisting of flakes made with direct percussion or bipolar percussion. Bipolar percussion involved striking the top of a cobble resting on an anvil stone, enabling the transmission of force from both “poles” of the cobble (Fig. 4). Unmodified bipolar flake tools, or those flaked into slightly refined forms, were “amorphous” in form, and their production resulted in a miscellany of chunks and shards. Some argue that this technology was nonspecialized (Clark & Lee, 1984) and required limited skill (Clark, 1981). It allowed the knapper an easy means to maximize the amount of available cutting edge in areas where obsidian was a scarce and distant resource. More recently, however, evidence

Stone Tools in Mesoamerica:

Stone Tools in Mesoamerica: Flaked Stone Tools,
Fig. 4 The bipolar percussion technique (Illustration by Karen Andrews. Used with her permission)

from the Olmec site of San Lorenzo supports the notion that rather than scarcity, it was used primarily for reducing relatively small pieces of obsidian that are otherwise difficult to flake

(De León, 2008). Moreover, it did require much more skill than has been previously appreciated. This expedient technology is found in Mesoamerica from the Basin of Mexico (Boksenbaum, 1980; Tolstoy, Fish, Boksenbaum, Blair Vauhn, & Smith, 1977) to the Pacific coast of Guatemala (Fig. 1) (Coe, 1961).

Although expedient techniques were prevalent well into the Preclassic (2500 BCE–AD 300) period (Aoyama, 1994, p. 136; Clark, 1987), some Postclassic sites (AD 900–1521) also have bipolar artifacts (Andrews, 2013). Recent research at the Aztec site Calixtlahuaca indicates that bipolar reduction was a limited but significant component of the city's flaked stone economy (about 10 %). It was used to reduce small nodules of obsidian and to further process “used up” bifaces and prismatic blades and cores (Fig. 5). Scalar cores might have provided flakes for various uses, but their relatively thin, V-shaped longitudinal profiles suggest that they may have functioned as wedge-type tools. The identification of bipolar prismatic blade segments was most surprising. The technique created new sharp cutting edges and “burinated” fracture surfaces good for scraping. Evidence of a similar use of bipolar percussion was also identified at the Aztec site of Xico in the Basin of Mexico (Brumfiel, 1986, p. 258). Its great time depth is consistent with the additive nature of

Stone Tools in Mesoamerica:

Flaked Stone Tools,

Fig. 5 Bipolar artifacts from Calixtlahuaca: (a) “scalar” bipolar core; (b) bipolar blade sections, dorsal surfaces *top* row, ventral surfaces *bottom* row (Photos by author)

culture – early technologies are often never completely replaced; they just become supplementary to their newer counterparts. Bipolar reduction was probably used elsewhere but has gone under reported because few researchers have looked for it in Post-Formative archaeological collections.

Mesoamerican Blade Technology

Even though a few pressure blades may have been made in Central Mexico after 3400 BCE, blade production did not become prominent until the Middle Preclassic (900–300 BCE) period

(Hirth & Flenniken, 2002, p. 123). The factors responsible for the emergence of the Mesoamerican blade technology remain a topic of debate (see “[Extra: Origins of the Mesoamerican Blade Technology](#)”). By the time socially complex societies like Teotihuacan (AD 100–650) and Xochicalco (AD 650–900) (see Fig. 1 for site locations) had emerged, blade production had become a specialized occupation carried out by skilled craftsmen. Teotihuacan, located near the Basin of Mexico (Fig. 1), had an impressive population of 125,000 people by AD 500, most of whom performed their domestic cutting and piercing activities with blade tools. As such, evidence for specialized blade production has been

used to study the complexity of this society's economy (Andrews, 2002, 2012; Hirth & Andrews, 2006; Millon, 1973; Spence, 1981, 1987). Recent research has examined the skill of blade makers to determine how often they worked (see “[Extra: Measuring the Skill of Ancient Blade-Making Craftsmen](#)”).

The Mesoamerican blade technology resulted in the production of similar types of tools, although production techniques definitely varied. This variation can be attributed to numerous factors including distance to obsidian sources, the quality of different types of obsidian, how it was acquired (e.g., directly from the source, in the marketplace, etc.), different production techniques, and localized demand for specific types of products (Hirth & Andrews, 2002). Hence, readers must keep in mind that the following sequence is a generalized ideal; all local reduction sequences were to varying degrees unique.

In general, blades were detached from cylindrical cores using percussion and pressure techniques. Obsidian was acquired from quarries in the form of blocks and nodules and as cobbles in stream deposits (Spence, 1981). The initial step involved making a core platform. A platform is the surface where force was applied to remove blades. Large platform preparation flakes were detached from the upper end of the pending core (Fig. 6). This procedure created a smooth concave surface on a core preform. Sometimes platforms were further modified with pecking and grinding (see “[Extra: The Pecked and Ground Core Platform](#)”).

Next, relatively large decortication flakes and macroflakes were detached from the lateral sides of the core preform (Fig. 6). Decortication is the removal of the cortex or weathered surface of the stone. Additional macroflake detachments gave the preform more symmetry, resulting in a primary macrocore with irregular ridges on its lateral facets. Some of these macrocores are immense measuring more than 40 cm in length (Fig. 7), although most of them fall in the 15–20 cm range. After initially shaping the macrocore, macroblades were removed from the primary macrocore to make a secondary

macrocore (Fig. 6). Macroblades were relatively long, parallel-sided items with one or more dorsal ridges. These blades were roughly 2.5 cm wide and more than 1 cm thick. By themselves, macroblades were sturdy cutting implements, but they were also further shaped into more specialized biface tools (Fig. 8). Macroblade removal created a series of parallel, irregular ridges running the length of the core. Next, small percussion blades were detached to make the polyhedral core (Fig. 6). These blades are thinner than macroblades, with widths of less than 2.5 cm, and their removal created more regularized parallel ridges running the length of the core.

Most initial core shaping and blade-making activities were accomplished with direct percussion. Indirect percussion, however, was also probably used. This technique involved placing one end of an antler, bone, or wood punch on a platform and then striking the opposite end with a hammer stone; it permits more precise control over the transmission of force than direct percussion (Fig. 9). As a consequence, relatively standardized percussion blades can be made with indirect percussion. Although still a subject of debate (Pelegrin, 2003), the recovery of extremely symmetrical macroblades at sites like Kaminaljuyu in the Maya region (Fig. 1) suggests that indirect percussion was used in ancient Mesoamerica (Hirth, 2003).

The polyhedral core was reduced to make the delicate pressure blades that were common place in ancient Mesoamerica. The Aztec technique for making these blades has been reconstructed according to historic information and replication experiments (Clark, 1989c; Crabtree, 1968; Sahagun, 1963, plate 778; Titmus & Clark, 2003; de Torquemada, 1975; Tudela & Corona Nuñez, 1977). The reconstruction proposes that seated craftsmen secured cores against an immovable object with their feet and then used their stomach muscles and torso to “press” or push blades off with a long-handled wooden stick called an *itzcolotli* (Fig. 10). In some areas of Mesoamerica, however, pressure blades were also removed with a handheld technique (Flenniken & Hirth, 2003).

Stone Tools in Mesoamerica:
Flaked Stone Tools,
Fig. 6 Schematic diagram of the initial steps in core production (Illustration by author)

First-series blades were the initial pressure blades removed from a polyhedral core (Fig. 11). These blades eliminated irregular ridges left by the blades previously removed with percussion. Sometimes second-series blades were taken off after first-series blades depending on the shape of the polyhedral core. If the core was cone shaped, first-series blades often extended only part way down the sloping core face, resulting in a secondary polyhedral core.

In turn, second-series blades were removed to extend the parallel ridges the entire length of the core.

The product of first- and second-series blade detachments was the pressure core (Fig. 11). Pressure cores yielded third-series blades that are generally regular and consistent in shape (width and thickness) and have two dorsal ridges, thereby making them prismatic in cross section. The dorsal ridges were mechanically important

Stone Tools in Mesoamerica: Flaked Stone Tools, Fig. 7 Large macrocore from the Zaragoza-Oyameles obsidian quarry in the Mexican State of Puebla (Photo by Charles Knight. Used with his permission)

because they helped guide the transmission of force from the platform resulting in successful pressure blade removal.

Many pressure blades were further modified in a variety of ways. Most of them were snapped into sections and used for cutting activities. One parallel edge could be hafted in a piece of wood or bone, making the section easier to handle. A piece of wood or bone was incised deep enough to insert the blade section, which was then secured with a sticky adhesive composed of pine pitch and ashes.

Pressure blades were also made into specialized forms such as projectile points, lancets, and notched silhouettes of various forms. Small pressure blade projectile points were used for hunting and warfare. Many of these items were too small

Stone Tools in Mesoamerica: Flaked Stone Tools, Fig. 8 Broken macroblade biface tools discarded at a blade-making workshop at Teotihuacan (Photos by Alejandro Serabia. Property of the author)

to be propelled effectively with a spear thrower (Fig. 12a, b). Consequently, their size and minimal weight indicate that they were used to tip arrows propelled with a bow. This conclusion is interesting because small blade points occur in archaeological deposits that supposedly predate the Postclassic (AD 900) introduction of the bow in Mesoamerica (see [“Extra: The Bow and Arrow in Prehistoric Mesoamerica”](#)).

The slender needle-like, lancet blades (Fig. 12c–e) may have been used in textile production, but they were most important for blood-letting. Historic sources and ritual archaeological contexts where lancets have been found indicate that they were used to draw blood (Clark, 1989d, p. 314; Durán, 1971, p. 263; López de Cogolludo 1954; Motolinía, 1950; Nuttall, 1903; see Landa in Tozzer, 1941, pp. 113–114). Lancets are often portrayed in bloodletting rituals depicted on Mexican and Maya codices, Maya

Stone Tools in Mesoamerica: Flaked Stone Tools, Fig. 9 The indirect percussion technique (Illustration by Karen Andrews. Used with her permission)

monuments, and polychrome vessels. As an act of auto-sacrifice, this practice was essential for appeasing the gods by providing them with blood nourishment.

Silhouettes, usually referred to as “eccentrics,” were also made from pressure blades and occur in a variety of shapes including crescents and trilobal sections (Fig. 12f–h). Here, the term silhouette is preferred to eccentric because the latter literally means “without symmetry” – most of these artifacts have symmetry and should be referred to by terms more specific to their morphological, technical, and functional attributes (Alejandro Pastrana, personal communication, 2014). Pressure blade silhouettes may have functioned as ornamental elements, perhaps signifying social status, which were sewn on articles of clothing (Spence, 1996). Their symbolic significance is supported by their relatively high frequency in burials and ritual cache deposits.

The end by-product of the blade-making sequence was the exhausted pressure core, often measuring no more than 1.5 cm in diameter (Fig. 11). At some sites like the Aztec city of Otumba (Otis Charlton, 1993) and the pre-Aztec city of Xochicalco (Fig. 1), lapidary craftsmen used exhausted cores to make beads (Fig. 13). The slender cores were fractured into sections using bipolar percussion and then ground and polished to perfection.

Mesoamerican Biface Technology

Biface flaking techniques were used to make impressive biface and uniface items for domestic, military, and ideological purposes. Although probably made by individual households early on, by the Classic period (AD 300–900), many of these implements were being made in specialized workshops at the quarries or in the cities. One important utilitarian uniface artifact in Central Mexico was the maguey scraper (Fig. 14). The maguey plant (*Agave atrovirens*) was a valuable source of water, food, fiber, and fuel, among other things (Evans, 1990; Sauer, 1963; Sheehy, 2001). Near Teotihuacan, large maguey scrapers at the Aztec (AD 1350–1520) period site of Cihuatecpan were made of relatively coarse obsidian from the source of Otumba (Fig. 1). Maguey scrapers were used to process maguey fibers and to initiate the flow of a sticky liquid that was converted into a fermented drink called *pulque*. Evidence suggests that pulque was a valuable source of nutrition and potable liquid in large cities like Teotihuacan where sanitation was a serious problem (Sheehy, 2001, p. 265).

Large, impressive bifaces were used for combat and also may have had symbolic significance given the central importance of warfare, conquest, and human sacrifice that emerged during the Classic period (AD 300–900) (Fig. 15). These items occurred in many forms. At Teotihuacan (AD 100–650), evidence has indicated that the large atlatl points for the city’s army were made by craftsmen under the direction of state officials (Carballo, 2004, 2007). During the Epiclassic period (AD 650–900), evidence suggests that

Stone Tools in Mesoamerica:

Flaked Stone Tools,

Fig. 10 Gene Titmus removing pressure blades using an Aztec *itzcolotli* (Photos by James Woods. Used with his permission)

numerous biface workshops in and around Teotihuacan may have supplied many consumers in the region and beyond (Andrews & Hirth, 2006, p. 249; Nelson, 2009, p. 160).

Like the small silhouettes made from pressure blades, the contexts in which their large counterparts are found indicate that they had symbolic significance (Gamio, 1966; Moholy-Nagy, 1989; Stocker & Spence, 1973). At Teotihuacan, some of the most impressive examples are the anthropomorphic silhouettes (Fig. 16). Other impressive pieces combine multiple symbols into one implement, such as a projectile point, a serpent, and a trilobal motif signifying blood droplets (Fig. 17). Many of these items were undoubtedly associated with warfare and sacrifice because they are often recovered in offerings with human sacrificial victims decorated as warriors.

At Xochicalco, ten impressive silhouettes were found atop the site's major public pyramid.

They occur in several forms including circular uniface elements (Fig. 18). These artifacts were either used during public rituals conducted for the benefit of the masses or were the contents of dedicatory caches buried during the construction of the pyramid.

The stone tool technologies prevalent in pre-Hispanic Mesoamerica varied over both time and space. This discussion has provided a cursory overview of the flake stone tools prevalent from Paleo-Indian period (prior to 7200 BCE) until the Spanish conquest in the early sixteenth century. The Mesoamerican blade technology was the most important, enabling the production of prismatic blades that were further shaped into different types of tools. Overall, flaked stone tool production in Mesoamerica provided a remarkable variety of highly functional implements used for a variety of activities.

Extra: Obsidian in Mesoamerica

Obsidian is an igneous stone that is often described as “volcanic glass.” This siliceous material is created by the extremely rapid cooling of volcanic ejecta, a process that prevents the formation of crystalline structure. Obsidian is very smooth and glassy to rough or grainy in texture and is usually black to gray in color, but

it also can be red, brown, green, silver, and aqua-marine. This variation in color is the result of chemical impurities. Obsidian occurs in block or tabular form in large veins or as isolated chunks and cobbles in flows of volcanic material. It can also be found on talus slopes or alluvial streambeds in a “weathered” cobble form. Having eroded out of primary geologic context, the weathered cobble

surface exhibits tiny cones or fracture planes that are produced by rolling action. Obsidian is easy to work with because of its noncrystalline structure, and it produces an extremely sharp cutting

edge. One disadvantage of obsidian is that it is brittle, so that tools and tool edges can break more easily than other flakeable stone like chert and flint.

Stone Tools in Mesoamerica:

Throughout most of Mesoamerica, obsidian was the primary raw material used to make flaked stone tools. In the region, obsidian flows are found in two major zones of geologically recent volcanism (Glascok, Elam, & Cobean, 1988). One major zone is an east-west trending band of sources scattered from the state of Veracruz on the Gulf of Mexico to the western state of Michoacán bordering the Pacific Ocean; well-known sources in this zone include Pico de Orizaba, Zaragoza-Oyameles, Sierra de las Navajas (Pachuca), Otumba, Zacualtipan, Ucareo, Zinapécuaro, and La Mora/Teuchitlan (Fig. 1). The southern zone is located in Guatemala, El Salvador, and western Honduras; well-known sources in this zone include Jilotepeque, El Chayel, Ixtapeque, and Esperanza (Fig. 1).

Studies of obsidian artifacts from archaeological sites using techniques such as instrumental neutron activation analysis (INAA), X-ray fluorescence (XRF), and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) have revealed that large quantities of these materials were transported across the landscape. By tracing the distribution of different sources, archaeologists have been able to reconstruct routes of obsidian trade and transport and how

they changed over time (Asaro, Michel, Sidrys, & Stross, 1978; Boksenbaum, Tolstoy, Harbottle, Kimberlin, & Neivens, 1987; Braswell & Glascock, 1998; Cobean, Vogt, Glascock, & Stocker, 1991; Glascock, Elam, & Aoyama, 1991, 1994, Glascock, Neff, Stryker, & Johnson, 1994; Hirth, 2008; Knight & Glascock, 2009; Moholy-Nagy, 2003; Nelson, 1985).

Extra: The Ideological Significance of Obsidian

Thus far, comparatively little attention has been given to research on the ideology related to obsidian flaked stone tool production. Ideology or belief systems are the most challenging for the archaeologist to reconstruct. But, the general theoretical perspective embraced by many archaeologists posits that technological and economic features of a society are linked to ideological aspects of culture (Erickson & Murphy, 2008). Even though obsidian provided essential tools,

Stone Tools in Mesoamerica:

Stone Tools in Mesoamerica: Flaked Stone Tools,
Fig. 18 Crescent silhouette from Xochicalco (Photo by author)

it also had an extremely complex symbolic conceptualization in ancient Mesoamerica.

Often mined underground, obsidian was associated with the underworld, the land of the dead, and other valuable resources like water and precious metals (Pastrana, 1998, pp. 174–189). The Aztecs believed it was created when a bolt of lightning (male symbolism) struck a sacred cave (female symbolism) and thus represents a product of the union of heaven and earth. It had a similar origin story for the ancient Maya and was considered the Heart of the Earth (Heyden, 1988, p. 220). Human use of this sacred stone took on numerous forms of ritual significance. For example, warriors fought with weapons of obsidian, which meant they were metaphorically the ones who “carried divinity with them.”

One important god in the Aztec pantheon was *Tezcatlipoca*, who embodied four aspects represented by different colors, each one patron of a different part of the universe (Solís, 1994,

p. 185). Black Tezcatlipoca was related to the underworld, sacrifice, and of course obsidian, and his idols in the main temples were made of this material (Heyden, 1988, p. 222; Pastrana, 1998, p. 179). Associated with the night, sorcery, and warfare (Berdan, 2005), he was arguably the most respected and powerful of all the gods (Heyden, 1988, p. 222). Tezcatlipoca was the protector of rulers and ensured their strength – he spoke to the people through their rulers. Another symbol associated with Tezcatlipoca was the obsidian mirror, which had divinatory properties. Tezcatlipoca was referred to as Smoking Mirror, depicted with one on his forehead and his right foot. The obsidian mirror provided him with a reflection of everything that took place in the world.

Another prominent Mesoamerican deity was *Itzpapalotl*, the Obsidian Butterfly, an ancient goddess married to the hunting god *Mixcoatl*, revered by the Aztecs as a warrior who led soldiers into battle (Heyden, 1988, p. 220). Moreover, she and her obsidian knife were symbols for human sacrifice. Her title and importance may have been related to the belief that warriors who died in battle returned as butterflies.

A deified form of the Aztec sacrificial obsidian knife was the god *Itztli*, one of the nine principle gods of the Underworld. As such, the obsidian knives, at least those used for sacrifice, were considered supremely divine symbols of blood sacrifice, a practice that was essential for maintaining the stability of the Mesoamerican universe. Also, *Itztli* may have been the *Nahuatl* (language of the Aztecs) word for obsidian blades and is the prefix for the name of the prismatic blade removal tool (*Itzcolotli*) referred to in the text above.

The entire sequence of obsidian stone tool production and use also was associated with different gods (Pastrana, 1998, p. 190). Aztec miners who obtained obsidian from underground quarries were protected by the god *Ehecatl-Quetzalcoatl*. This god was associated with fertility and water, which was considered a resource that emanated from the underworld via the springs and caves of mountains. Interestingly, a sculpture of *Ehecatl-Quetzalcoatl* was

recovered from one Aztec mine at the Sierra de las Navajas (see Fig. 1) quarry in Central Mexico (Pastrana, 1998, p. 192). Craftsmen involved in the initial shaping of obsidian blade cores and bifaces at the quarries were protected by *Itzpapalotl*. Besides sacrifice, she was also associated with mother earth and possibly the mythical origin of obsidian (Sullivan, 1972). City-based craftsmen who further shaped obsidian implements were associated with *Papaloxahual-Xochipilli*. This deity was patron of the arts and perhaps craft guilds, especially those that produced sacred items like obsidian mirrors (Pastrana, 1998, p. 190). Not surprisingly, those involved in military activities were under the protection of Tezcatlipoca and *Itzpapalotl*, who was often depicted on the shields of warriors.

The symbolic significance of obsidian was extremely complex, and this brief summary provides a glimpse of how an important facet of material culture was tied to, or otherwise justified by, Mesoamerican ideology. Clearly, our understanding of this topic comes largely from ethnohistoric accounts of the Aztecs and Mayans recorded around the time of the Spanish conquest. The gods and symbols, however, have much greater time depth. Although we cannot assume the meanings were exactly the same for earlier societies like the Toltecs and Olmecs, ethnohistoric data and the archaeological context of artifactual symbolism can be used to infer the meaning of the latter. This realm of study is limited, but it represents an exciting new research focus that scholars are beginning to examine with greater interest (Levine & Carballo, 2014). It is important because it adds to our holistic understanding of ancient societies, a hallmark of anthropological archaeology.

Extra: Origins of the Mesoamerican Blade Technology

Hirth and Flenniken (2002, p. 123) have pointed out that research on the origins of the Mesoamerican blade technology has been limited. Initially emerging during the Middle Preclassic (900–300 BCE), by 700 BCE prismatic blades had become

the primary flaked stone tool from the Central Highlands to the Chalchuapa area of El Salvador (Aoyama, 1994, p. 174; Clark & Lee, 1984; Coe & Diehl, 1980, pp. 247–249; Grove, 1974, p. 33, 48; Marcus & Flannery, 1996; Pires-Ferreira, 1975, Table 5; Sheets, 1978b, Tables 3 and 5; Sweeney, 1983, p. 619).

William Parry (1994) and John Clark (1987) are two researchers that have addressed the emergence of this technology from a largely theoretical perspective. Their views are somewhat complementary, but they emphasize different factors. Parry (1994) suggests that the principal motivating factor may have been a demand for the production and exchange of many uniform, standardized implements. A blade technology enables such outputs, but a relatively high level of skill is required to make large batches of standardized blades efficiently. Hence, an increasing demand for blades during the Middle Preclassic created a need for blade-making craftsmen. These specialists supported themselves, at least in part, by exchanging blades at the regional and perhaps interregional level. He further notes that many blade workshops are found in large settlements with monumental architecture, sometimes quite distant from obsidian sources. Parry (1994, p. 94) tentatively states that this evidence may indicate that early craftsmen were attached or sponsored by the ruling elites in these large settlements.

Clark (1987) suggests that the widespread adoption of the Mesoamerican blade technology was related to the competitive elite behavior associated with ranked or chiefdom societies. These societies differed from the Archaic foraging groups (7200–2500 B.C.) in that people lived in larger sedentary communities that were socially hierarchical. Clark (1987) maintains that there was no real technological advantage to a blade technology because the expedient flake tools made during the Archaic period were functionally adequate. Moreover, the Mesoamerican blade technology required specialized training because it was difficult to learn. It also required the coordination of core production at the source and the transport of cores to the settlements where they were reduced. Consequently,

Clark (1987) suggests that the adoption of the Mesoamerican blade technology was complex enough to require the sponsorship of the elites who ruled the Preclassic ranked or chiefdom societies. Accordingly, these elites financed and organized the acquisition, production, and distribution of cores to blade-making craftsmen in large settlements.

Many researchers have debated various reasons why blade technologies arose in different space and time throughout the world. The Parry (1994) and Clark (1987) models for the emergence of Mesoamerican blade technology cannot be used to explain the adoption of blade technologies in societies that were less complex than chiefdoms (Hirth & Flenniken, 2002). World-wide examples include the Paleolithic and Neolithic blade technologies of Europe, Asia, and North Africa (Inizan & Lechevallier, 1990; Pelegriin, 1997; Tixier, 1976), the Paleolithic microblade technologies of Siberia and Japan (Flenniken, 1988; Kobayashi, 1970), and the microblade technologies of North America (Andrefsky, 1987; Arnold, 1985; Bradley & Yevgeny, 1996; Magne, 2004; Morrow, 1988; Parry, 1994; Rasic & Andrefsky, 2001; Reid, 1976; Yesner & Pearson, 2002). These societies ranged from highly mobile to relatively settled groups who probably never attained the level of social complexity typically associated with chiefdoms.

The adoption of blade tools in northwestern North America may relate to functional aspects of the technology (Yesner & Pearson, 2002). This argument recently summarized by Magne (2004, p. 94) states that microblades were a “response to any of several possible causes, such as lithic raw material shortage alleviated by efficient blade production, preference for composite slotted armaments, or resource uses for which microblade design is most efficient, such as slicing, peeling, piercing...” It has also been suggested that blade technologies may be best suited to societies where the tasks involved in food acquisition or production (subsistence tasks) were predictable (Rasic & Andrefsky, 2001, p. 77). Here the manufacture of standardized blade “replacement” parts for tools

repeatedly used for the same tasks would be technologically efficient.

The development of craft specialization and exchange (Parry, 1994) and the competitive elite behavior associated with emerging chiefdom societies (Clark, 1987) may have played a role in the adoption of the blade technology in some places of Mesoamerica. However, new empirical evidence from the Olmec site of San Lorenzo (Fig. 1), arguably the first large-scale Mesoamerican community with monumental architecture, indicates early blade production was independent of elite involvement (K. Hirth & A. Cyphers, personal communication, 2014). Its inhabitants had relatively equal access to obsidian, and the only evidence for blade production is found on the periphery of San Lorenzo Island, a great distance from San Lorenzo's elite-controlled center. Hence, if elites were not initially involved in the emergence of this technology, the functional argument that blades are better for economies with predictable subsistence tasks deserves consideration. The Mesoamerican Preclassic period (2500 B.C. – A.D. 300) was associated with a profound shift from small-scale foraging societies to larger settled chiefdom societies. Hence, compared to the nomadic foraging lifestyle during the Archaic period, the daily tasks associated with settled agricultural economies during the Preclassic were certainly more predictable because they were tied to the strict seasonal cultivation of specific crops. Moreover, the patchy distribution of obsidian across the landscape would have made a blade technology more effective for supplying the needs of large settlements with tools from distant sources. Craft specialists producing highly standardized blades for specific tasks would have been able to efficiently meet the needs of very large settlements.

Extra: Measuring the Skill of Ancient Blade-Making Craftsmen

In ancient Mesoamerica, obsidian blades were made by specialized craftsmen. Some researchers have attempted to measure the skill of these craftsmen as a means for identifying how much

time they devoted to blade-making activities (Andrews, 2003, 2012; Clark, 2003; Clark & Bryant, 1997; Hirth & Andrews, 2006). Defining the time spent making blades is important because it helps archaeologists infer how many blades were in demand and how much economic exchange there was between members of an ancient society. This kind of information reflects the complexity of a society's economy. Unlike the modern world where everyone specializes in a particular job, most prehistoric societies were primarily composed of people who provisioned themselves with all their daily needs. As societies became larger, people began to specialize in different occupations and exchanged their products for things they did not produce. Hence, the level of specialization in a society is a measure of economic interdependency (Durkheim, 1933).

Measuring craftsman skill is founded on the assumption that aptitude should vary according to the amount of time invested in blade production; in other words, highly skilled craftsmen should be those who made the most blades. Essentially, this assumption is based on the premise of practice makes perfect.

Measuring the skill of ancient blade-making craftsmen in Mesoamerica is quite a challenge. The one advantage to studying flaked stone artifacts is that they are made with a reductive technology. That is, flaked stone tools are shaped by reducing or removing pieces of stone from a larger stone until the desired form is achieved. The pieces that are removed are called by-products. Careful study of the by-products of Mesoamerican blade production has made it possible to identify those artifacts that are mistakes, items that represent one means for measuring craftsman skill.

Mesoamerican blade craftsmen usually made blades in household workshops. Several artifacts found at these workshops have been identified as mistakes; these items include the hinge-fractured blade and the plunging blade. A hinge-fractured blade is a blade that failed to extend all the way to the bottom of a core. The distal end of a hinged blade has a fracture plane that curves outward from its ventral to dorsal surface (Fig. 19a). These artifacts are mistakes because the

Stone Tools in Mesoamerica:

Flaked Stone Tools,

Fig. 19 Hinged and plunging artifacts from the site of Xochicalco: (a) hinged blade section; (b) core exhibiting severe hinge scars; (c) plunging blade section (Illustration by the author. Property of Kenneth Hirth. Used with his permission)

craftsman's intent was to remove a blade that extended the entire length of the core. Also, hinged blades leave behind a deep scar that inhibits the removal of subsequent blades from that part of the core (Fig. 19b).

A plunging blade removes the distal tip of a core. In contrast to the hinge fracture, a plunging blade's ventral surface curves inward at the bottom of the core thereby removing more core length than intended (Fig. 19c). This mishap reduces the length of subsequent blades, thereby reducing the overall amount of cutting edge that can be produced from a core. The forces resulting in the production of these mistakes are described in detail elsewhere (Andrews, 1999, 2003; Clark & Bryant, 1997; Santley, Kerley, & Kneebone, 1986; Sheets, 1978b).

It has been suggested that the frequency of mistakes in a collection of by-products should be useful for measuring the skill of flaked stone tool craftsmen (Clark, 1986, 2003; Sheets, 1975, 1978b; Torrence, 1986, p. 147). Consequently, comparisons of hinged and plunging blade frequencies from Mesoamerican blade workshops have been used to make comparative assessments of skill. Workshops with the highest level of skill have the fewest errors.

Preliminary assessments of craftsman skill at the immense Classic period (AD 100–650) city of

Teotihuacan and the smaller Epiclassic (AD 650–900) city of Xochicalco indicate that Teotihuacan's craftsmen made fewer mistakes (Andrews, 1999, 2012). Hence, based on the assumption that skill varied in relation to time spent in production, it appears that Teotihuacan's craftsmen made and exchanged more blades than the craftsmen at Xochicalco. This finding fits previous characterizations of Teotihuacan's economy as being highly complex, with many specialists throughout the city dependent to a significant degree on nonagricultural production for their livelihoods. In contrast, Xochicalco's economy appears to have been less complex, with more limited evidence of craft production and economic interdependence (Hirth, 2000). In this way, measuring the skill of flaked stone tool producers has contributed to supporting earlier inferences about economic complexity.

Extra: The Pecked and Ground Core Platform

Another source of variation in the Mesoamerican blade technology was core platform treatment. Sometimes single-facet platforms were pecked

and ground, creating a flatter, slightly rough surface. This type of platform became widespread during the Postclassic (AD 900–1519) period, but it emerged in the preceding Epiclassic (AD 650–900) period and perhaps was present even earlier in some areas of Mesoamerica. The pecking and grinding of platforms took place during different phases of the reduction sequence throughout the region. For example, at Tula (Fig. 1), the capital of the Toltec empire, platforms were pecked and ground at the macrocore stage, whereas at Xochicalco, an Epiclassic (AD 650–900) city, they were pecked and ground on small, already partially reduced prismatic cores.

The pecked and ground platform modification made blade removal easier for two reasons. First, the tiny fracture cones produced during the pecking stage made blade removals easier. Experiments indicate that less pressure force is needed because the tiny microfractures help to facilitate a macrofracture, permitting successful blade removal. This outcome of the process was extremely important, especially at sites like Epiclassic (AD 650–900) Xochicalco where blades were detached by hand from very small (>8 cm in length) prismatic cores (Flenniken & Hirth, 2003). Experiments have demonstrated that it is difficult to generate enough force with the handheld technique to produce successful blades using cores longer than 8 cm in length. Second, the pecked and ground surface reduced the risk that the pressure tool used to remove blades would slip off the platform. This outcome aided the craftsman in the precise application of force.

Extra: The Bow and Arrow in Prehistoric Mesoamerica

The date when the bow and arrow became prevalent in prehistoric Mesoamerica is still a subject of debate. The established date for the introduction of the bow in North America is sometime around AD 200, much earlier than what is generally accepted for Mesoamerica. Citing a lack of archaeological and iconographic evidence for the

bow, Hassig (1992) has suggested that it did not become common in Mesoamerica until the Postclassic (AD 900–1519) period. Other researchers, however, have suggested that the bow was present during the Classic (AD 300–900) period (Linné, 1934) or perhaps even earlier during the Preclassic (2500 BCE–AD 300) period (Tolstoy, 1971).

One reason for believing the bow was common in Mesoamerica prior to the Postclassic period is the presence of small projectile points (>3 cm in length, Fig. 12b) at many sites predating AD 900. Many of them were fashioned out of prismatic blade sections that were made with pressure. The use of these implements as effective tips for spears or *atlatls* (spear throwers) is hard to imagine because they are so small. Indeed, research indicates that many *atlatl* points average over 4.5 cm in length (Thomas, 1978, p. 469). As a result, it has been suggested that small points found in mortuary offerings at Classic period Teotihuacan may have had a ceremonial or ideological significance (Parry, 2002).

Although small points predating the Postclassic period may have had a ceremonial function, research at the Epiclassic (AD 650–900) city of Xochicalco suggests that such items were used to tip arrows (Andrews & Hirth, 2006). This conclusion supports earlier claims that the bow was present at Epiclassic Xochicalco (Sáenz 1961, pp. 40–43, 1967, p. 10, 14) and at the contemporary site of Cacaxtla (Fig. 1) in the modern state of Tlaxcala (Baus de Czitrom, 1986, p. 529). Most of the small points at Xochicalco have been found throughout the city in nonceremonial contexts. In addition, they comprise the entire collection of projectile points ($N = 83$) recovered in the city's public armory. Hence, there is little doubt that these points were used to tip arrows, and given the central importance of militarism and conquest at Xochicalco, they were probably used for combat.

Acknowledgements This article benefited from the assistance of various organizations and individuals. The artifacts from Xochicalco were recovered and analyzed with support from the Foundation for Mesoamerican

Studies, Inc. (FAMSI grant 01029), the Proyecto Especial Xochicalco (directed by Norberto González Crespo) funded by the Instituto Nacional de Antropología e Historia, and the Xochicalco Lithic Project (directed by Kenneth Hirth) funded by National Science Foundation research grants 9429292, 9496188, and 9121949. Analysis of the Calixtlahuaca Project (directed by Michael Smith) was supported by National Science Foundation research grants 0618462 and 0150482, and Regency and Wang Center grants from Pacific Lutheran University. The macrocore (Fig. 7) is from the The Zaragoza-Oyameles Regional Obsidian Survey, Puebla, Mexico (directed by Charles Knight), funded by the National Science Foundation grant BCS-1063233. Karen Andrews, Constantino Armendariz, David Carballo, Susan Evans, Luis Gonzalo Gaviño, Timothy Scheffler, Alejandro Serabia, Saburo Sugiyama, Gene Titmus, and James Woods provided invaluable assistance with many of the figures. Finally, I appreciate the ideas and editorial feedback from David Carballo, Frances Berdan, Ann Cyphers, Silvia Domínguez, Susan Evans, Haley Harms, Kenneth Hirth, Charles Knight, and Alejandro Pastrana.

Stone Transport of the Olmec

Leslie C. Hazell

Institute of Latin American Studies, La Trobe University, Melbourne, VIC, Australia

The legacy of large stones left by prehistoric societies has often led to debate, conjecture, and speculation that link cultural or belief imperatives to structural form and using materials moved from sometimes distant sources. Our uncertainty extends to explaining how ancient people moved these large stones or megaliths weighing many tons, using simple tools in contrast to today's modern equipment. Limited archaeological evidence encourages debate, and even when there is visual evidence, differing arguments and interpretations can be raised (Photo 1).

In Mesoamerica, stones moved by Olmec society during Preclassic times posed such a question, with megaliths, most weighing between 5 and 20 t, transported a distance of at least 80 km. The source for the stones included Cerro Cintepec near the Tuxtla Mountains in Veracruz state of modern Mexico. Besides the stones themselves, little archaeological evidence was available to understand or explain the transport process. The larger stones were used for sculptures known as *cabezas colasales*, or colossal heads, and also altars, and thrones with many smaller stones were used for other sculptures. The more likely method was considered to be water transport using a combination of sleds and raft configurations made of canoes or logs. Direct land routes held challenging obstacles of seasonally fast flowing rivers, extensive swamps, and floodplains and so were discounted (Fig. 1).

More recently this view of water transportation has been challenged, suggesting land transport was not only possible, but is in fact the more likely method. This research used a different research methodology and database of watercraft performance and behavior under load in seagoing conditions. These data were applied to human capability and physiology. To examine land

transport, analytical tools available with GIS technology were adapted to study the question. The parameters for this aspect of the study also utilized human physiology data. In doing so, the methodology overcame the limited application of replication experiments and has shown that applying this approach to existing data provides useful outcomes.

San Lorenzo Olmec and Stone Heads

When introducing the Olmec, researchers often refer to the Olmec as the “mother culture,” a title that is debated. What is not disputed is the Olmec “heartland,” a sphere of influence some 200 km long and 80 km wide (125 × 50 miles). At its heart during the period between 1200 and 900 BC known as the Preclassic was the San Lorenzo (SL) plateau, the political hub. Situated some 60 km (38 miles) from the Gulf of Mexico, the SL plateau is a partly man-made ridge around 1,200 m long and rising some 45 m above the extensive floodplains and swamplands, characteristic of the Rio Coatzacoalcas basin. Its position and elevation make the plateau a dominant feature over this area, underwritten by the agriculturally productive floodplains that supported the general population and its hierarchy comprising artisans and rulers. The latter resided exclusively on the SL plateau and initiated the manufacture of the stone and jade objects, found not only on the plateau but also elsewhere in the region. Jadeite was sourced from distant sites by trade or exchange, but volcanic stone was used for the larger sculptures including the colossal heads. These are apparently the likeness of different rulers, conferring value on the stone used, with at least one head originally an altar. Such value underwrites the need for a viable transport process and a favorable agricultural situation nurturing manpower resources required to transport the stones and carve the heads.

An early and valuable study by Velson and Clark (1975) established specific transport elements of water transport, including raft types, manpower needed, and possible routes. However, testing this work with updated analytical

Stone Transport of the Olmec, Photo 1 Colossal head at Xalapa Museum of Anthropology:
L. Hazell 2008

Stone Transport of the Olmec, Fig. 1 Hypothetical water transport routes (Drawn by L. Hazell 2008)

techniques, adopting environmental and maritime data as parameters, and applying them to human physiology subsequently redefined Olmec stone transport, in particular the unlikely use of open water routes and methods (Fig. 2).

The methodology determined prevailing wind speed and direction generated a wave size, frequency, and speed that would overcome canoe raft configurations, while ocean surface currents would be in excess of the ability of hypothetical Olmec crews to make progress. This power constraint also occurs traveling upstream to the SL. Increasing crew numbers would not overcome this nor would using known sail

configurations. The question of viable progress against current flows in both situations was even more pronounced with log rafts. As water transport was not practical, the previously dismissed land routes were reinvestigated.

The challenge of the Olmec heartland terrain, in particular swamps, floodplains, and gradients, were constraints adopted as parameters. In practical and viability terms, these translate into the need of human power (drafting animal power was not a fact of Olmec life) and ingenuity to overcome, particularly to haul or control stones on slopes. In addition soils must be capable of bearing the load of the stones or at least being changed

Stone Transport of the Olmec, Fig. 2 Differential Forces. Drawn by L. Hazell 2008

so they could the required load. Human power is known from experimentation and replication. Ethnohistoric examples provide further data as well as an insight into possible methods. These examples show, as a parameter, a gradient value of 1:10 adopted in analysis defines human numbers needed for control and whose combined power can be effectively coordinated. Adopting these and a terrestrial database established by digitizing Instituto Nacional de Estadística y Geografía (INEGI) survey maps and using slope gradient analysis defined viable land routes within a corridor that also included a known workshop at Llano del Jicaro. Quarry sites were also included in this corridor even though the stones were not quarried in the accepted sense (Fig. 3).

The analyses also provided a starting point for pathways to cross the floodplains and swamp areas and ultimately access the SL plateau. These areas are seasonally inundated making crossing them apparently implausible. However, laboratory testing of soils found on the plains and tested as wet and dry samples was compared with both causeway and natural levee core samples. The results indicated the bearing capacity of the predominant alluvial silts (Barro Veteado) while theoretically a constraint to viable transport crossing, would not be so in reality.

Stone Transport of the Olmec, Fig. 3 Geographic information systems (GIS) slope gradient analyses: L. Hazell. Deep red pixels indicate steep gradients: modern roads generally follow lesser gradients indicated by pale pixels

The differences between wet and dry resistance suggested that a seasonal constraint on transport would apply though (Fig. 4).

This constraint could be overcome. Structural examples demonstrated that the Olmec were accomplished earth builders, possessing the knowledge to construct durable structures such as the San Lorenzo and Tenochtitlan plateaus,

S

earth mounds, platforms, and causeways. Modern civil engineering understands that structural deficiencies or durability limitations in soil properties can be overcome by mixing different soil types. From strata identified in known earth structures, the Olmec were apparently aware of this as well. The layering found in these structures combines soil of differing types and properties similar to that used on modern road building. This made earth structures a likely tool to move megaliths from the Tuxtla Mountains to San Lorenzo and

a logical application of strength or compressive resistance knowledge.

Yet even without applying this knowledge to causeways, silts found on the floodplains provided sufficient compressive resistance for their transport without using these additional materials. Nevertheless a constructed pathway of this soil is subject to seasonal conditions although without durability, a property not needed for singular or irregular megalith transport. Even so Olmec earth structure durability is clearly

Stone Transport of the Olmec, Fig. 5 Summary of soil strength calculations with applied megalith weight

Compression resistance of soil strata from lab tests:

Core 8 DRY: 12132kpa (average)

Core 8 WET: 124kpa (average)

$$\text{SL 1: weight 25.3 short tons} = 22947\text{kg} \times 73\% = \frac{39698\text{kg} \times 9.81}{6.58}$$

$$= 59.18\text{kpa}$$

$$\text{using a sled: } \frac{39698\text{kg} + 2034 \times 9.81}{2.49}$$

$$= 164\text{kpa}$$

Summary of soil strength calculations with applied megalith weight

demonstrated by the Potrero Nuevo causeway, on which the present-day village of Loma del Zapote is built.

Calculations using the laboratory data confirmed that a megalith transport process that involved sliding along the ground would not deform the soil, while a sled would do so, increasing resistance to hauling (Fig. 5).

By using these outcomes with slope gradient analyses, it was reasonable to assume that land transport was more likely, especially when this route held less risk than the uncertainty of watercraft performance and structural integrity in open waters. The same compressive resistance also defined methods to move the stones, as dragging the stones in contact with the path allowed the weight to be spread under the deformation level of the soil. Any other method such as a sled or using rollers to move stone around 20 t would exceed this point. Not all stones were this heavy though, and a method using a “y” frame for stones of around 1–2 t proved to be viable.

In refining Olmec stone-moving methods, the flattened rear of the heads appears to reinforce the notion of direct contact hauling. This shape allows stable hauling while minimizing deformation of the underlying road surface during the process (Fig. 6). Linking the combined power of the haulers is one further element in this equation, as rope is represented on the sculptures and known for the period. The numbers of haulers

Stone Transport of the Olmec, Fig. 6 Colossal head showing the flattened back: Xalapa Museum of Anthropology (Photo: L. Hazell 2008)

used varied depending on specific gradients and stone size, while the agricultural economy could support the numbers needed to haul megaliths.

These workers, combined with their artisan and Olmec hierarchal power, are components of Olmec megalith use and their transport, but a further element is the application of knowledge to build the structures that is still visible today. Research of the stone transport process with this methodology allows us to appreciate this knowledge.

Stonemasonry of the Incas

Jean-Pierre Protzen

University of California, Berkeley, CA, USA

And what one admires most is that, although these [stones] in the wall I am talking about are not cut straight but are very uneven in size and shape among themselves, they fit together with incredible precision without mortar. (Acosta, lib. 6, cap. 14; 1962: 297)

Like Father Acosta in the seventeenth century, the modern traveler stands in awe before the Inca walls of huge stones, some weighing over 100 metric tons, tightly fitted together. They wonder about how people who did not know the wheel and had no iron tools transported and dressed stones of that size and mated them one to another in such a way that, as the saying goes, not even the blade of a knife could be inserted into the joints. Answers to these questions have been replete with speculations ranging from the intervention of extraterrestrial beings, the use of parabolic mirrors concentrating sunlight to cut the stone laser-like, to the application of an herb, the juice of which softened the stone, to the more prosaic investment of an immense labor force. Recent studies of Inca construction, however, demonstrate that the awe-inspiring, tightly fit megalithic masonry was well within the technological reach of the Incas (Protzen, 1985, 1986, 1993). It is to be hoped that the fantastic tales of extraterrestrial intervention will be put to rest once and for all.

Quarrying

The Incas did not practice quarrying in the proper sense. The stone is neither cut off a rock face nor is it detached from bedrock by undercutting. The Incas gained their building stone either by picking suitable blocks out of a rockfall or by prying it loose from fragmented rock faces. Large blocks of five or more tons were only minimally shaped in the quarries; all the fine work was done at the

construction site. Smaller building blocks were dressed on most sides in the quarries, and only the finishing and the fitting to other stones was reserved for the site.

The Incas chose the stones to be quarried with great care. Proper workability, texture, and color of the stone mattered a great deal. Rocks also had symbolic, even religious, significance for the Incas, which may explain why they often went far out of the way from a construction site, to quarry the appropriate stone. According to some chroniclers, stones from the andesite quarries of Rumicollca, some 30 km south of Cuzco, were not only used in the construction of Cuzco but were shipped all the way to Tomebamba in Ecuador, some 1,700 km to the north. Research by Dennis Ogburn (2004) lends credibility to this story: the petrological compositions of the stones at Tomebamba very closely match that of the stones from Rumicollca. To access the quarries and transport the stones, the Incas built well-engineered roads, 4–5 m wide. For example, to get a specific rose rhyolite for the so-called Sun Temple at Ollantaytambo and to reach the quarries of Kachiqhata, the Incas built enormous ramps, the total construction volume of which exceeded the volume of quarried stones by a factor of 40 or more. This is the price the Incas were willing to pay for a select stone.

Cutting and Dressing

To cut and dress stones, the Incas used simple river cobbles of various sizes as hammers. These tools and their fragments are found in abundance in the ancient quarries scattered among roughed out building blocks and in the quarrying waste. The hammerstones are easily distinguished from other stones by both their shape and their petrological characteristics; they are water-worn rounded stones of materials different from the quarried stone and the surrounding bedrock. The hammers come in different sizes; some are as small as an egg, others are the size of a football, and others still are two to three times the size of an American football. The largest of these hammerstones were used to break up and roughly

shape the raw stones, the medium sized to dress the faces of the building blocks, and the smallest to draft and cut their edges and corners. The technique involved is exactly as Garcilaso de la Vega “El Inca” described it: “The quarryfolks, . . . , who had no other instruments to work the stones, but some black cobbles they called *hihuana* (sic. for *hihuaya*), with which they dress the stones by bruising rather than cutting” (lib II, cap. XXVIII, 1976, p. 119, tomo I).

Indeed, when hitting the workpiece straight on with a hammerstone, one crushes the rock producing little more than dust. However, if one increases the angle of impact to about 15–20°, little chips can be torn off. By further increasing the angle to some 45° by imparting a twist to the hammer just before impact larger chips can be removed, thus accelerating the process considerably. The impact of the hammer leaves a small pitmark on the workpiece. Such pitmarks can be observed on every face of every building block in every Inca wall of cut stones, regardless of the building blocks’ material. Smaller, finer pitmarks found along the edges of the building blocks indicate that smaller stones were used to cut the edges. The particular technique in cutting edges requires that the edge be shaped by hitting the workpiece with grazing blows directed away from the workpiece, which results in corners with dihedral angles larger than 90°. It is these obtuse angles that account for the characteristic beveled joints of Inca cut stonemasonry and that brings about the *chiaroscuro* effect.

Extensive experiments have demonstrated that the process is relatively easy, effective and precise, and not as time consuming as one might assume. Twenty quarry people working side by side could dress a block 4.5 m long, 3.2 m wide, and 1.7 m high – the dimensions of one of the largest building blocks in the ancient quarry of Kachiqhata near Ollantaytambo – in less than 15 days.

Fitting

The most intriguing question about Inca cut stonemasonry concerns the precision fitting of

the blocks. It has been repeatedly argued that the Inca stonemasons ground the blocks into place using a mixture of sand and water. The evidence, however, does not support this hypothesis. Where walls have been dismantled or fallen apart, one finds the exact imprint of the stones which have been removed or fallen off. Very often the shape of the imprints determines a unique position for the stone it once accommodated. To grind in a stone, however, requires that the stone can move freely along a path in at least one direction. Thus, the ground stone would fit in any, and not just one, position along that path. Furthermore, if the stones had been ground into place, the joints should show signs of abrasion, but they do not. Instead one finds the typical pitmarks which result from pounding.

The imprints seen on dismantled walls indicate that when laying a wall, the Inca stonemasons left the top face of every new course uncut until it was to receive a new course. The bottom face of the block of the new course was cut first, and a suitable bed was carved out of the course already in place. A similar approach was used for the rising joints; it is the side of the block already in situ that was carved to match the pre-cut shape of its new neighbor. The technique used appears to have been one of trial and error. The masons started by outlining the shape of the new stone atop the course it was to be fitted to and proceeded to carve out a bed. By trying the fit time again and again, the masons obtained a perfect match. Granted, the trial and error technique is a tedious one and perhaps not very convincing if one considers megalithic building blocks of several dozens of tons. However, it works and does not postulate the use of tools and machinery of which no traces have been found. The Incas had plenty of time and manpower at hand. Since they moved huge blocks over many kilometers, it is not inconceivable that they were capable of setting up a stone several times to achieve the desired fit. It is of course also conceivable that the Inca stonemasons knew of another technique to transfer the shape of one stone to another without actually trying it in successive steps. Such a technique has in fact been proposed by Vincent Lee (1986). Inspired by log

cabin builders, Lee suggests that the shape of one stone was scribed onto the other with an ingenious but simple device consisting of a stick and a plumb bob. Although experiments have shown the technique to work, there is no evidence as of yet that the Incas actually used it.

Assemblage

When assembling a wall, the Incas often had several construction crews working simultaneously and side by side. Where two crews met in a course, the final gap in the wall was closed with a “wedge” stone introduced into the masonry bond from the front of the wall. Because in the last gap there is not enough room to maneuver the stones for the usual one-on-one fitting, the Inca stonemasons hit on the ingenious idea of the wedge stone that fits to its neighbors only along a very narrow band near the face of the wall. Once one knows what to look for, it is relatively easy to spot wedge stones in an Inca cut-stone wall and to determine its construction sequences. If scribing had been the predominant fitting technique, there would have been no need for wedge stones: even the last stone could have been scribed for a perfect match and lowered into place. But many wedge stones clearly were not lowered into the gap they were intended to fill, since they are generally wider at the bottom than at the top.

Transporting

Another vexing problem is how the Incas transported and heaved enormous building stones. Rough abrasion marks found on building blocks at Ollantaytambo suggest that the stones were simply dragged along the ground. From these marks it is even possible to determine the direction in which the blocks traveled. The dragging of big stones is consistent with chroniclers’ reports:

These Indians used to move very large stones with muscle power, pulling them with many long ropes of lianas and leaf fibers, . . . and they [the stones]

are so big that 15 yokes of oxen could not pull them” (Gutierrez de Santa Clara lib. 3, cap. 63, 1904–1929, p. 550). Dragging big blocks involves large transportation crews: “Four thousand of them were breaking stones and extracting stones; six thousand were hauling them with big ropes of hide and leaf fibers; . . . (Cieza de León cap. LI, 1967, p. 170)

Six thousand people dragging a stone is not unreasonable; many Old World transportation problems were solved with very large work forces. Engelbach (1923), for example, calculated that it would have taken 6,000 men to haul the unfinished obelisk at Aswan from the quarries to the Nile. The questions raised by a transportation crew as numerous as this, which remain largely unanswered, are how the crew was harnessed to the stones and how it negotiated turns on the narrow roads on the steep slopes of the Andes.

An experiment carried out in 1994 in the town of Ollantaytambo involved the dragging of a 14 metric ton heavy Inca building block a distance of about 150 m. One hundred and eighty-four people from the town, men and women, volunteered for the task. They were given no instruction regarding how the task had to be performed. They brought ropes, which they wrapped around the block like a net in such a way as to have six leading ropes extending from the stone in the direction it was to be pulled. The 184 people were distributed over the six leading ropes, which they grabbed and leaned into to drag the block the requisite distance with relative ease over a surface roughly equivalent to the roads from the quarries.

How smaller stones, like those from the quarries of Rumicollca, were transported remains uncertain. The general assumption is that the stones were either carried on litters or that they were suspended from poles carried on peoples’ shoulders.

To lift stone up onto a wall under construction, the Incas built ramps perpendicular to the wall and raised the ramps as the wall got higher. At Sillustani near Puno on Lake Titicaca, such a ramp leaning against an unfinished burial tower, called *chullpa*, can be seen today. According to the Jesuit priest Bernabé Cobo,

this practice was still in use in the construction of the cathedral in Cuzco. He reported that "... since they lacked cranes, wheels and engines to lift them [the stones], they made a steep ramp attached to the work over which they raised them; as the edifice was growing they raised the ramp; this device I saw in use at the cathedral of Cuzco that is being built; because the masons who work on this construction are Indians they let them ... use what they are accustomed to ..." (tomo II, libr. XIV, cap. XII, 1964, p. 262).

Antecedents

John Hemming argued emphatically that the high skills of the Inca stonemasons "cannot have been developed in the century or less of Inca ascendance. Architecture anywhere in the world evolves from precursors" (1980, p. 26). Here, the precedent is Tiahuanaco at the south end of Lake Titicaca, which reached its peak around 900 C-E. Tiahuanaco has some of the world's finest stonemasonry: carefully fitted rectangular ashlars [masonry made of large square-cut stones, typically used as a facing on walls of brick or stone] and exquisitely worked monolithic gates and statues. It is said that Pachakuti, the 9th Inca, was so impressed by this stonework when he first saw Tiahuanaco that he advised his architects to take careful note of how this masonry was made because he wanted Cuzco to be built in the same manner. It is also said that he imported Qolla laborers from the Lake Titicaca area to work on construction projects (Sarmiento de Gamboa cap. 40, 1943, pp. 111–112). But because Tiahuanaco culture developed at least a millennium before the Incas, and may have reached its peak some five to six centuries before Pachakuti's rise to power, and because nothing comparable has been built in the interim, one may question why the Qolla laborer should remember any of the ancient techniques. More recent research by Protzen and Nair (1997) shows that there exist significant differences between the architecture and stonemasonry of Tiahuanaco and that of the Incas, suggesting that,

although the Inca may indeed have been inspired by Tiahuanaco, their architecture and stonemasonry were authentic inventions.

String and Stories

David Turnbull

Architecture Faculty, Victorian Eco-Innovation Lab (VEIL), Melbourne University, Melbourne, VIC, Australia

Elizabeth Barber in her classic *Women's Work: The First 20,000 Years* made the profound observation:

We don't know how early to date this great discovery - of making string as long and as strong as needed by twisting short filaments together... Soft flexible thread of this sort is a necessary prerequisite to making woven cloth. On a far more basic level, string can be used simply to tie things up - to catch, to hold, to carry. From these notions come snares and fishlines, tethers and leashes, carrying nets, handles, and packages, not to mention a way of binding objects together to form more complex tools... So powerful, in fact, is simple string in taming the world to human will and ingenuity that I suspect it to be the unseen weapon that allowed the human race to conquer the earth, that enabled us to move out into every econiche on the globe during the Upper Palaeolithic. We could call it the String Revolution. (1994, p. 45)

Barber's insight that the capacity to join things together through lashing, binding, and knotting, with string or cordage, is what gave people mobility is of profound importance. It cannot, however, have occurred in isolation from two other essential capacities: bodily movement and communication. How and why human movement is accomplished is central to our understandings of the growth and transmission of culture and civilization and is thoroughly social and embodied. Movements are always performed by groups of people through the actions of their own bodies and are coordinated and motivated through ritual, music, dance, and stories. Movements through the landscape also create trails both cognitive and material. "We know *as we go*" (Ingold, 2000, p. 230). Historically stories, string, and trails were very likely coproduced with one another; they certainly inform each other mythopoetically through the fundamental commonality of narrative, journeying, and weaving.

Weaving and storytelling reflect a common origin in the derivation of text and textile from the Latin verb *texere* to weave.

The linguistic remnants of the body in movement and action can be dimly perceived in the root meanings of many terms closely associated with making meaning and knowing. Take, for example, understand – in Old English to grasp an idea by standing or placing the body in between. Similarly epistemology, the study of what can be known, comes from the Greek *epi* meaning over and near and *histasthai* to stand, that is, to know through putting oneself in a good position. Symbol – something standing for something else – comes from the Greek *bolein* to place or throw together. Likewise a metaphor was literally a device for being transported across space; in modern Greek a *metaphor* is a taxi. Theory originally meant to contemplate, from *theoros*; in modern Greek it is one who travels to see things, an ambassador. Travel was originally travail, to work, and method comes from *meta* and *hodos* – after the traveling way.

What weaving, stories, and string share is the complex duality of tension and connection, difference and similarity. Stories join ideas, string joins things together, and both are dependent on tension. String and cordage derive their connective capacity from tension in knots, binding, or twining, and tension derives from the Sanskrit word for string. Weaving and textiles depend on the tension between the warp and the weft.

Stories and narratives are dialogical and have an essential tension or irony that comes from the listener's implicit double recognition that the coherence, the order the storyteller imposes on the world, comes from linking things together while also recognizing that entirely contradictory orderings and associations are equally possible and that in relating one narrative in terms of another stories are told and understood against the background tradition of other stories. Stories are a way of dealing with the ontological multiplicity or "bothness" of life, the tensions and incommensurabilities between the contingent and the ordered, between the anomalous and the classified, between differing subjectivities, spatialities, and temporalities, and between the

personal and the theoretical, the concrete and the abstract, the essential contradictions, and the inexpressibility of human existence (Pelton, 1980, p. 258). The trickster myth, that is common to so many cultures, reveals the multiplicities and tensions in the way the human world is storied and performed through language. In Norse mythology, for example, the links are apparent in the role of Loki the trickster god of mischief and destruction who also taught mankind the art of netting (Turner & van de Griend, 1996). In Greek myth it was Athena the goddess of many things but especially love, procreation, wisdom, civilization, strategy, and weaving (Barber, 1994, p. 241).

Barber's insight that string, an almost invisible and seemingly trivial soft technology, gave humans the capacity to move requires a radical rethinking of the stories we tell ourselves about the origins and nature of human civilization and existence. Archaeology has, until now, celebrated early cultural development as basically lithic (related to stone) and technological, a process based in utilitarian stone tools and weapons, giving us a rather androcentric (centered or focused on males) picture of early man conquering the world with stone axes. Focusing on string brings into prominence the catching of small birds, animals, and fish through netting. It emphasizes the capacity for movement of humans by land and by sea. Most importantly it brings into visibility the early development of nonutilitarian ornamentation and symbolization. These capacities for enabling symbolic expression, mobility, and relatively low key methods of hunting and tracking give a very different perspective on the early development of technology and culture. But, there are profoundly differing views about whether all these constituted a "revolution" occurring in the Paleolithic period around 26,000 BP as Barber believed or whether they occurred considerably earlier and more incrementally. If so, string was not a human innovation but a hominin one.

There is now strong evidence that string was made by Neanderthals, and possibly even *Homo erectus*. Bruce Hardy and his team have found twisted fibers in a rock shelter very near the

Chauvet cave in France that they date at 90,000BP (Hardy, 2008; Hardy et al., 2013). Two key areas in which the early uses of string are evident are in very ancient shell beads and in new datings of the earliest movements by sea. Recent discoveries of clusters of beads and pendants with drilled holes reveal the necessity of the almost invisible technology of the string, thread, cord, or fiber to suspend them. At the same time they suggest the development of a capacity for reflection and symbolization, for abstraction and communication. Such capacities are normally taken to be prototypically human, but there are some archaeologists who date ostrich shell beads in Africa as far back as 200,000 years ago (Bednarik, 1997a, 1997b, 1997c). Recent finds, at Blombos in South Africa, of pierced shell beads showing signs of wear by threads or clothing are dated at around 75,000 years ago, and maybe as old as 280,000 (Douglas, 2004, p. 26). Dating disputes will always permeate archaeology, but it is clear that Neanderthals made necklaces implying symbolization and least protolanguage (Arsuaga, 2002). The other and most important development was traveling by boat across open-sea passages. Australian Aborigines were once thought to be the world's first sailors, arriving in Australia across an ocean gap of around 50 km at least 60,000 years ago. Water transport over this breadth of deep water would require string of some sort in the form of lashing and knots to tie together what was most probably a bamboo raft (Jones, 1989; Thorne & Raymond, 1989, p. 39ff). Now this claim has been supplanted by evidence of stone tools on Crete and Cyprus dated at over 100, 000 BP and on Flores at over 1 Ma BP (Brumm et al., 2010; Simmons, 2014; Strasser et al., 2010).

The earliest direct evidence we have currently for string as twisted plant or animal fiber and hence as the basic component of clothing or textiles is 26,000 BP, and there are figurines wearing string skirts which are dated around 20,000 BP. The use of twisted cords for weaving on looms has developed from the earliest times in cultures around the world from the Andes to China (Adovasio & Hyland, 2000), as has the

use of knots for mnemonics and decoration and the celebration of string in games and stories. Perhaps the most highly elaborated use of string was in the *quipu* of the Inca. Gary Urton's research suggests that these knotted strings were examples of how something as simple as string is capable of generating a hugely complex system of signification, codification, and narrative (Urton, 2003; Quilter & Urton, 2002; Salomon, 2004). Similarly Weiner (2001, p. 236) suggests that the *kirugu*, the sacred knotted cord of the Iatmul of the Sepik in Papua New Guinea, maps out the stories of their migrations.

String, stories, and trails, in their complex interactions and their multiple embodied skills and practices, now stand among the earliest of technologies and were developed by our hominid ancestors, all of which should give us pause in our contemporary storytellings that locate our cultural origins in developments of symbolic and social technologies around 35,000–40,000 BP. Our cultural origins now look much less gendered, much less modern, much less Eurocentric, and much less special to humans (Villa & Roebroeks, 2014). We and our ancestors created trails, traveled by water, and joined ideas and things together, making ourselves and our world.

Suanxue Qimeng

Karine Chemla

Laboratoire SPHERE UMR 7219 (ex-REHSEIS)
Case 7093, Université Paris 7 - CNRS, Paris,
France

The *Suanxue qimeng* (*Introduction to Mathematical Studies*), the first book composed by Zhu Shijie, a Chinese mathematician of the Yuan dynasty, was published in 1299 (Du, 1966; Ho, 1970–1980). It differs from his second one, the *Siyuan yujian* (1303), in that its mathematical content presents a stronger continuity with the Chinese mathematical tradition. Most of the topics treated in it can be traced back to the Han classic which founded this tradition, the *Jiuzhang suanshu* (*The Nine Chapters on Mathematical Procedures*, hereafter called *The Nine Chapters*), probably completed in the first century AD. Indeed, Zhu Shijie deals there with the rule of three, the distribution into unequal parts, and their composition or reiteration along the lines

opened by the sixth of *The Nine Chapters*. He also describes how to perform the same computations with fractions and presents algorithms to obtain areas and volumes, even though he considers some forms not found in *The Nine Chapters*. The rule of excess and deficit, which was transmitted to the West where it became known as the rule of false double position, receives in his *Suanxue qimeng* a presentation as complete as in *The Nine Chapters*, even though it had been partially forgotten and sometimes transmitted in an imperfect state during the time elapsed since the composition of the latter (Chemla, 1997). Moreover, Zhu Shijie devotes a chapter to an improved presentation of the algorithm for the solution of systems of simultaneous equations given by *The Nine Chapters* and comparable to the so-called Gaussian pivot method (Chemla, 1992, 1996).

In addition to this, the *Suanxue qimeng* includes the treatment of topics that had emerged in the previous decades in Northern China, Zhu Shijie's homeland, such as the "procedure of the celestial unknown," a technique that puts into play polynomial algebra to obtain an equation to solve a given problem (Du, 1966).

Yet, in contrast to *The Nine Chapters*, Zhu Shijie, in the first part of the book, makes clear which algorithms can be used to perform the basic arithmetical computations on the counting surface and includes new procedures for such computations when particular numbers are involved. It is interesting that some of the procedures he described could be used later without change when the abacus replaced the counting surface. In this respect as in others, such as the treatment of topics like the summation of all kinds of series, the inclusion of tables of unit conversion, a style of practicing mathematics in close contact with the problems of socio-economic life, or the use of certain new technical terms, the *Suanxue qimeng* repeatedly evokes the writings of Yang Hui, a mathematician who had lived slightly earlier in Southern China (Lam, 1979). Indeed, in contrast to the period before the unification of China under Mongol rule, when mathematics seems to have developed independently in the north and the south of China, the time of unification when Zhu Shijie

worked might have allowed the partial merging of these two traditions; his book may be our first reflection of this (Du, 1966).

Sugar in Latin America

Judith Vidal

The sucrose from sugar cane is identical to that in beet sugar and other sugars such as glucose, dextrose, fructose, levulose, and lactose. The chemical formula for sucrose is the oligosaccharide C₁₂H₂₂O₁₁. After refining, sugar is 99.9 % pure.

Sugar cane was first cultivated and processed in India thousands of years ago. Gradually, medieval trade routes brought the product and its cultivation to the Mediterranean basin and Madeira where it languished on a small scale until its introduction to the Caribbean and Brazil. Columbus took it to Hispaniola on his second voyage in 1493. Cortés took it to New Spain, Balboa to Central America, and Pizarro to Peru. It was in Brazil, however, that the efforts of Duarte Coelho Pereira converted his captaincy of Pernambuco into a prosperous sugar-producing center fashioned after the *engenhos* (sugar works) of Madeira from whence the first cuttings and processing technology came. This became the model for an industry so vital to Portugal they courted Dutch capital to finance the African slave trade to supply the necessary labor. In exchange, the Lowlands received the crude sugar for refining and distribution. So profitable was this arrangement that the Portuguese eventually abandoned their enterprises in the Far East for the Brazilian milk cow, as Emperor João III fondly referred to the flourishing colonial sugar industry.

Aside from the introduction of large-scale cultivation and processing, the techniques of sugar production changed little since the early days of Venetian and Dutch refining and trading monopolies. Cultivation was usually from small cuttings or ratoons planted in evenly spaced furrows and allowed to mature for periods from 6 to 18 months – depending on the type of cane, the time and amount of rainfall or irrigation, temperature, storms, quality of soil, disease, and pests.

Plantation owners and managers were constantly alert for crop dangers and began to employ technicians to advise them. They experimented with irrigation systems, tested new strains of cane from both seed and ratoon, and tried crop rotation. Harvest had to follow immediately upon maturation. Normally this was by hand-held machetes wielded by slave laborers. Sometimes they used slash-and-burn techniques.

Harvesting was simultaneously accompanied by manually loading the syrup-filled stalks into mule-drawn carts for transport to the sugar houses. The cane was then handfed through the

vertical or horizontal cylindrical presses which were originally adapted from wooden olive presses. These were two- or three-roller, metal-clad, devices with gears powered by humans or animals (*trapiches*) or water (*engenhos*). The extracted syrup flowed through wooden troughs or, in some cases where capital and topography permitted, through Roman-style aqueducts to the boiling sheds. Large *engenhos* comprised thousands of acres with thousands of residents in self-sufficient hacienda communities. More modest enterprises relied on hand-carrying the crude syrup to nearby pots for boiling.

Early production systems were ecologically complete, for the crushed stalks (or bagasse) were dried and used as fuel to fire the boiling vats. The ashes and extraneous leaves and stalks were tilled back into the soil as fertilizer and also served as animal fodder. Slaves found that unprocessed molasses from pieces of stalk that were not disposed of quickly underwent inversion and began fermentation; this primitive rum was used as currency to reward slaves and keep them cooperative but was not recognized as a commercial product for export.

Until the nineteenth century, the juice from the raw cane went through a series of open-pot boilings at extremely high temperatures. This process was watched very carefully to avoid fire and to avert burning the sugar. Slaves ladled off the scum of debris which flocculated with animal grease at the top; other impurities settled to the bottom in sedimentation. Lime was then added to help clarify the syrup. This purification, also known as defecation, removed the maximum number of impurities. The clear syrup was then placed in evaporating pans. The sludge of megasse sugar was next scooped into hanging clay cones with open bottoms to allow the heavy brown molasses to drip out. The resulting crude sugar was about 96 % pure and fit for transport in casks or in loaves.

Shipped to European ports, crude sugar was sometimes sold directly, but most was transshipped and refined by a process of reheating in huge vats to which water and bone carbon filters were added. After a series of washings, the clear liquid was evaporated in copper pans

and allowed to crystallize or granulate – the finer the quality, the whiter the crystal. As with the processing of raw sugar, refining would remain unmodified until the nineteenth century introduced steam vacuums and centrifuges to the finishing processes.

Throughout the colonial period, every finishing process was done by the mother country or its agents, usually in the Lowlands. Therefore, refining always occurred in Europe. The most efficient refineries were scattered around Antwerp which remained the capital for finishing sugar until war razed the production centers and blockaded trade. Britain, France, and Germany then built their own refineries. Long before Britain took possession of sugar-producing lands, England monopolized refining and distribution industries. This availability of mass production coupled with a growing popular taste for sweetened coffee and bread with treacle (molasses) provided an amenable consumer base for the confection in England and on the continent which demanded the colonial product.

Having pirated the rattoons and seeds of Brazilian and Spanish haciendas, European powers sought to monopolize refining and trade. In 1662 Catherine of Braganza married Charles II of England; her dowry included former East Indian territories such as Bombay and Tangiers and also a taste for tea which swept the court with exceeding popularity and would eventually displace both coffee and cocoa as England's hot, sweetened beverage of choice.

The Caribbean was an entrepôt of plantation islands. England, Spain, Portugal, France, and Holland all engaged in slave trade with Africa, and all quickly learned the commercial value not only of sugar but also of its intermediary byproducts, molasses and rum. After the molasses dripped off the crude muscovado sugar, the syrup was fermented and distilled into rum on the islands as early as 1530 and used as currency to purchase African slaves. Molasses was shipped directly to North American ports where New England distilleries enjoyed a burgeoning business. From the time of the capture of Jamaica in 1655, rum was regularly issued to British sailors, for it lasted longer than the traditional ale on high

seas at certain temperatures. In 1754 it was watered down to grog and freely rationed until the 1960s. The sugar interest monopolized parliament and led to colonial uprisings which reshaped the empire.

Britain and its competitors consolidated their territories and introduced technological advances. As early as 1794, steam was used to power a three-roller press in Jamaica. A similar steam-driven mill operated in Cuba in 1797 – 10 years before the first successful steam-boat. These machines were neither uniformly nor extensively adopted and operated imperfectly. Early fixed iron rollers often clogged or broke when the woody stalks of older cane were fed through the press. Shutdowns were costly, for the syrup in cane spoiled if not processed within 3 days of harvest. Mechanical repairs and waiting for replacement parts also impeded production.

The vacuum pan was invented by Edward Charles Howard in England in 1813, but it was not introduced to the colonies until 1835. This pan admitted steam through holes in the pan's bottom which was lined by a filtering cloth and capped by a dome connected to an air pump with a condenser. Interior heating coils were added by Daniel Wilson, and in 1828 Louisiana planter Valcour Aime implemented these improvements in his sugar houses and also introduced the use of the polarimeter to value raw sugars in cane. Despite patent disputes a system of multiple evaporation in six to ten successive pans was widely adopted and diversely adapted throughout the world. Penzoldt's centrifugal machine invented in Germany in 1837 for drying wool was modified for sugar by Sir Henry Bessemer. Cane-processing technology was adapted for beet sugar. In London the Fairrie family experimented with decolorizing agents for their refinery and discovered animal charcoal.

With the mechanization of sugar in the latter nineteenth century came the professionalization of technical advisors and managers. Technical assistants had to know how to assemble equipment correctly, keep it in good repair, and operate it. Agricultural experts were consulted to identify the best strains of cane for a particular climate or soil. Hawaiian planters of the 1850s maintained

an experimental station which offered soil analyses, pathology reports, and pest controls. Entomological research at the British Museum identified natural predators and prescribed counter parasites.

The first mechanized harvests were successful in Australia. In the 1960s, Cuba contracted with Soviet engineers to develop a combine harvester. The self-propelled model ruined the ratoon and the ground for several seasons. Eventually the Cubans developed a harvester but technical problems diverted its production to Australia in 1984.

The sucrochemical industry experimented with research and development. Cane sucrose sales were eroded by beet sugar, high fructose corn sweeteners (HFCS) in processed foods, and synthetic sweeteners. New applications included gasohol, furniture, paper, and plastics. Brazil was the only successful producer of commercial gasohol although Australia and the US successfully converted their sugar industries to gasohol production during World War II.

The original sugar-producing countries of Latin America and the Caribbean still produce their crops of precious cane, but unstable governments, lack of capital, natural disaster, and inefficient management hinder technological growth.

Śulbasūtras

Manu V. Devadevan

Archive India Institute, Bhubaneswar, Odisha,
India

Sometime around the sixth century BCE, new forms of knowledge began to evolve in parts of northern India, aimed at preserving and cultivating the Vedic wisdom, worldviews, rituals, and practices. The body of knowledge thus produced was called *vedāṅgas* (organs/limbs of the Vedas) and classified under six distinct categories: phonetics (*śikṣā*), grammar (*vyākaraṇa*), metrics (*chhandas*), etymology (*nirukta*), astronomy and calendars (*jyotiṣa*), and rites, rituals, and sacrifices (*kalpa*). The last of these comprised prescriptive texts concerning ethics, morality and conduct (the *Dharmasūtras*), household affairs (the *Gṛhyasūtras*), and rituals (the *Srautasūtras*). Included in some of the *Srautasūtras* were guidelines for the construction of various fire altars (*citis*) and the arithmetic and geometrical formulae behind the process. These manuals were perhaps called *rajju samāsa* (“joining the measuring cord”). In course of time, they came to be identified as the *Śulbasūtras*.

Śulba, literally “string,” refers to the measuring cord, and *sūtra*, literally “string” again, means an aphorism in the Sanskrit technical vocabulary. We have information about 11 such “aphorisms of the measuring cord”: the *Baudhāyana*, the *Āpastamba*, the *Mānava*, the *Kātyāyana*, the *Maitrāyaṇa*, the *Hiraṇyakeśi*, the *Vādhūla*, the *Varāha*, the *Laugākṣi*, the *Satyāśadha*, and the *Maśaka*. The first eight of these are now extant. Later Vedic texts like the *Brāhmaṇas*, the *Āraṇyakas*, and the *Upaniṣads* were, as a rule, affiliated with one of the three Vedas. This was also the case with the *Śulbasūtras* or the *Srautasūtras* to which they were attached. The *Maśaka Śulbasūtra* belonged to the *Sāmaveda*, and the eight extant *Śulbasūtras* to the *Yajurveda* with the *Kātyāyana Śulbasūtra* pertaining to the *Śukla* (white) *Yajurveda* and the rest to the *Kṛṣṇa* (black) *Yajurveda*. *Śulbasūtras*

of the *Rgveda*, if they existed, have not come down to us.

The *Rgveda* speaks of fire as *triṣadhaṣṭha* or “dwelling in three places” (3.20.2). This might be a reference to *Gārhapatya*, *Āhavanīya*, and *Dakṣiṇā*, the three fires every household was expected to maintain. In premodern India, as in the rest of the premodern world, it was not possible – or at least not feasible – to produce fire everyday as it was a time-consuming process involving several hours of labor. Maintaining fire was the Vedic people’s answer to this challenge. They came up with the idea of maintaining a surplus of three fires in every household. The science of altar-construction doubtless developed to address this challenge. In course of time, the rituals evolved out of this functional matrix to become complex symbolic systems represented by rituals like the *agnicayana*. In response to this, the *Śulbasūtras* laid down guidelines for constructing such fanciful altars as the *rathacakra citi* (the chariot-wheel shaped altar), *śyena citi* (the falcon shaped altar), and the *kūrma citi* (the tortoise shaped altar). The symbolic significance of these rituals is so lost to us today that one scholar, Frits Staal, found them wanting in semantic content.

The *Śulbasūtra* mathematics is not very complex. It contains formulae for constructing basic geometrical figures like right angles, squares, rectangles, and trapezia. The construction of a square or a rectangle equal in area to other geometrical figures like a circle or a rhombus is of special interest to these manuals.

One such formula in the *Baudhāyana Śulbasūtra* describes how a circle is converted into a square, i.e., how a circular altar is rearranged to form a square altar of equal area. This is done by dividing the diameter of the circle into eight parts and an eighth part into a further 29 parts, from which 28 parts are removed in addition to a sixth part of it and an eighth part of the sixth part. The formula to convert a circle of diameter d into a square of length l will then be

$$l = d - \frac{d}{8} + \frac{d}{8 \times 29} - \frac{d}{8 \times 29} \left(\frac{1}{6} - \frac{1}{6 \times 8} \right) \\ = 0.87868d$$

Therefore, the area of the square is $l^2 = (0.87868d)^2 = 0.77208d^2$. The original area of the circle, with a π value of 3.141593, was

$$\pi r^2 = 3.141593 \left(\frac{d}{2}\right)^2 = 0.7854d^2$$

The area of the square and the circle ($0.77208d^2$ and $0.7854d^2$, respectively) are almost the same, the latter being larger by a mere 1.7 %.

The *Baudhāyana Śulbasūtra* gives a formula to arrive at the value of $\sqrt{2}$. Increase the length of a square by a third and the third in turn by a fourth. Reduce this by its 34th part. Thus,

$$\sqrt{2} = 1 + \frac{1}{3} + \frac{1}{3 \times 4} - \frac{1}{3 \times 4 \times 34} = 1.41422$$

which is a very close approximation to the correct value.

It is generally believed that mathematics in India evolved out of the *Śulbasūtras*. This, however, is not borne out by evidence. There is no influence of, or historical continuity or even a logical connection, between the *Śulbasūtras* and the later-day works of mathematicians like Āryabhaṭa, Mahāvīra, Bhāskara I, or Bhāskara II. The *Śulbasūtra* tradition came to an end by the turn of the millennium. This was due in large to the fact that the construction of altars for maintaining fire had outlived its historical destiny. Massive expansion of agriculture, which depended upon the availability of the bull and therefore the cow, facilitated surplus production of ghee (clarified butter) on a hitherto unprecedented scale. The production of oil, which was not heard of in the age of the *Ṛgveda*, was another concomitant development in the wake of agrarian expansion. Together, these enabled the maintenance of fire through the relatively easier means of perpetual lamps made of stone, clay, or metal. Not surprisingly, the three fires, consuming large quantities of smoke-producing fuel like wood, vanished from the households, taking away with them the science of the *Śulbasūtras*. Several centuries later, the Nampūtiri brāhmaṇas of Kerala revived the *agnicayana* and other sacrifices. But we do not know the context in which this revival

took place, or the meanings the Nampūtiris attached to the sacrifices, although they continue to offer glimpses of what transpired in the course of the sacrifices.

Sun Simo

Fabrizio Pregadio

The Chinese physician and medical author Sun Simo (alternative spelling: Sun Simiao) was a native of Huayan, in modern Shensi. His biography is so much a composite of fact and legend that it is even impossible either to substantiate or invalidate his traditional dates (581–682). From official, autobiographical, and hagiographic sources it emerges that he retired at an early age on Mount Taibai, not far from his birthplace. He repeatedly declined imperial summonses and official titles, but was almost certainly in Emperor Gaozong's retinue from 659 to 674, when he retired on account of illness. He seems to have spent an extended period in Sichuan, which may explain why many legends that concern him are located in that area. After his death he was venerated as *Yaowang* or “King of

Medicine” (by which he is still known) in temples dedicated to him.

Sun Simo is the author of two of the most important Chinese medical compilations, the *Qianjin fang* (Prescriptions Worth a Thousand or, Remedies Worth their Weight in Gold), also known as *Beiji qianjing yaofang* (Important Prescriptions Worth a Thousand, for Urgent Need), and the *Qianjin yifang* (Revised Prescriptions Worth a Thousand). The former, in 30 chapters, was completed soon after the middle of the seventh century (apparently in 652). The latter, also in 30 chapters, dates from the late seventh century. Both works are preserved in editions derived from versions published in the eleventh century, when they were edited to be used as textbooks in the Imperial Academy of Medicine. In these texts, Sun provides an extended compendium of contemporary medical knowledge, arranged in sections dealing with such subjects as pharmacology, etiology, gynecology, pediatrics, dietetics, acupuncture, ► [moxibustion](#), and specific diseases. Both texts include a wide selection of prescriptions (about 5300 in the *Yaofang*, about 2000 in the *Yifang*).

Among the many points of interest in these compilations, three deserve special mention. The first is the priority that Sun Simo accords to gynecology and pediatrics, the two branches of medicine with which he deals first in both works. The second is the importance given to medical ethics, reflected in this well known passage from the first chapter of the ► [Qianjin yaofang](#): “When someone comes to look for help, a doctor should not question rank or wealth, age or beauty, nor should he have personal feelings toward that person, his race, or his mental capacities. He should treat all his patients as equal, as though they were his own closest relatives.” The influence of Sun’s medical ethics spread beyond China, reaching Korea and Japan through quotations of relevant passages in texts of these two countries.

A third aspect is Sun’s relationship with Daoism (Taoism) and Buddhism. The nature of his involvement with the Way of the Celestial Masters (*Tianshi Dao*, one of the main traditions of liturgical Daoism) is debated. In the two chapters entitled *Jinjing* (Book of Interdictions)

of the *Qianjin yifang*, Sun quotes formulas used in exorcist rituals by the Celestial Masters. This raises the issue of how he gained access to them. His interest in Daoism is also reflected in the chapter on “Nourishing the Vital Principle” (*Yangxing*), and in another extant text on physiological disciplines which is attributed to him, the *Sheyang zhenzhong fang* (Pillowbook of Methods for Nourishing [the vital principle]).

Another source which points to Sun’s relationship with Daoism is the *Taiqing danjing yaojue* (Essential Instructions from the Books on the Elixirs of the Great Purity). This text -available in an excellent English translation – consists of a collection of alchemical methods, probably derived from the Six Dynasties compilations centered around the now lost *Taiqing jing* or Book of the Great Purity, one of the main early alchemical canons. Although Sun’s authorship cannot be definitively proved, we know from his own witness that he was involved in the compounding of elixirs around AD 610. Among the medical disorders which he experienced, of which he left a first-hand account in his medical works, is intoxication due to elixir ingestion.

In addition to Daoism, recent research has pointed out Sun Simo’s close connection with Buddhism. For example, he refers to Indian massage techniques, and mentions methods for the treatment of beriberi from works edited by Buddhist monks. Perhaps under the influence of Tiantai disciplines, he also introduced meditation in his medical practice. Moreover, the above mentioned “Jinjing” section of the *Qianjing yifang* includes incantatory formulas in Sanskrit. The main factor behind these Buddhist elements may have been Sun’s interest in the doctrines of the Huayan school. Some passages of his texts, especially those on medical ethics, acquire new meaning if read in this light.

Sun Tzu

Derek M. C. Yuen
Faculty of Social Science, Chung Chi College,
The Chinese University of Hong Kong, Shatin,
NT, Hong Kong

The Chinese military general, strategist, and theorist Sun Tzu was a notable historical figure in the late Spring and Autumn Period (770–403 BC) of ancient China. His birth name was Sun Wu (孫武), and he originated from a military family in the state of Qi (齊). His book *Sun Tzu: The Art of War* (孫子兵法) has been considered the most important military treatise of China, which laid the foundation of Chinese strategic thought and military dialectic and is widely applied in numerous fields worldwide today.

Despite his uncertain historicity, Sun Tzu was believed to be a contemporary of Lao Tzu (Lao Zi) and Confucius. Due to political upheavals in Qi, Sun Tzu moved to the state of Wu (吳). In 512 BC, Sun Tzu presented the King of Wu *The Art of War* (in 13 chapters) and was later appointed as a general. He played a major role in the war planning against the state of Chu (楚), Wu's arch-enemy. In 506 BC, Wu launched major offensives against Chu. Wu forces

commanded by Sun Tzu won a stunning victory and crushed Chu's main forces in the Battle of Boju (柏舉之戰) and captured Chu's capital, Ying (郢), as a result.

There was almost no historical record of Sun Tzu after the conquest of Chu. It was believed that Sun Tzu subsequently left Wu's court and chose to live in seclusion. Nevertheless, Sun Bin (孫臏), an alleged descendant of Sun Tzu who wrote *Sun Bin: The Art of Warfare* (孫臏兵法), emerged on the historical scene about 150 years later in the early Warring States Period (403–221 BC). In order to distinguish between the two, Sun Tzu was called "Wu Sun Tzu" (吳孫子, as he served the state of Wu) and Sun Bin "Qi Sun Tzu" (齊孫子, as he served the state of Qi).

The Art of War was written at a time when China was undergoing a period of tremendous changes that had led to the revolution in strategic thought. Sun Tzu's famous concept "war is the Tao (Way) of deception" marked the end of and departure from the old aristocratic way of war that was based on military rites. By recognizing "war is the Tao of deception," Sun Tzu developed various schemes to grasp the entirety of the situation for decision-making purposes as well as to precondition, manipulate, and eventually control the enemy.

Sun Tzu identified the presence of contradictions between phenomenon and essence in war as a result of the use of deception and stratagem. And accordingly, he devised a method to grasp the phenomenon that can help to infer the essence upon which strategists and generals can make their judgments and decisions. That is why Sun Tzu used so many contradicting pairs in *The Art of War*, including win–lose, strong–weak, attack–defense, vacuity–substance, numerous–few, and courage–fear, to represent any situation or circumstance so that generals and strategists can discern the abstract patterns and dynamic relations quickly and more easily (Li, Zehou, 2006, pp. 76–83).

One major theme of *The Art of War* is its emphasis on winning without fighting – "subjugating the enemy's army without fighting is the true pinnacle of excellence." This is made possible by exploring nonmilitary means in both

wartime and peacetime. “The highest realization of warfare is to attack the enemy’s plans; next is to attack their alliances; next to attack their army; and the lowest is to attack their fortified cities.” Even if a battle had to be fought, Sun Tzu advocated utilizing the dominant psychological/cognitive dimension in war by manipulating the enemy before entering a battle. He was against the idea that victory is solely decided by the battle itself – “the victorious army first realizes the conditions for victory, and then seeks to engage in battle. The vanquished army fights first, and then seeks victory.”

A dominant feature that contrasts *The Art of War* with Western military and strategic theories is its treatment of the relationship between theory and practice. Chinese strategic thought is not affected by the theory–practice relationship. It was modeled on no fixed model but water. Sun Tzu’s “water metaphor” – “the army’s disposition of force is like water . . . The army’s disposition of force avoids the substantial and strikes the vacuous. Water configures its flow in accord with the terrain; the army controls its victory in accord with the enemy” – rules out any possibility of predetermining events in accordance with a more or less definitive plan worked out in advance as an ideal to be realized (Jullien, 2004, p. 20). Nothing is essential except the demands of the situation, and the work of generals and strategists is to adapt to unfolding circumstances. As a result, they can avoid becoming bogged down on the one hand and can produce patterns that are never definite on the other hand.

Apart from being the cornerstone of the Chinese School of the Military (兵家) among other schools of thought, *The Art of War* constitutes an important basis for Chinese pragmatism and rationalism, which had influenced the development of Taoism and Legalism (Realism) significantly (Li, Zehou, 2006, pp. 83–106).

Sun Zi

Ang Tian Se

Of all the mathematicians in ancient China, we know the least about the life of Sun Zi. The fact that he was given the honorific designation of *Zi* (Master) after his surname led some people like Zhu Zunyi (AD 1629–1709) to identify him with Sun Wu, a celebrated tactician in the sixth century BCE. Then Ruan Yuan (AD 1764–1849) assigned him to the late Zhou period of the third century BCE. With regard to the text written by Sun Zi, Dai Zhen, the eighteenth century scholar and mathematician, citing from internal evidence, argued that the text could not have been written earlier than the Han dynasty at the turn of the Christian era. Though this text by Sun Zi was listed in all the bibliographical chapters of the *Sui Shu* (Standard History of the Sui dynasty), the *Jiu Tang Shu* (Old Standard History of the Tang Dynasty), and the *Xin Tang Shu* (New Standard History of the Tang Dynasty), there was no mention of its author. This shows that as early as the middle of the seventh century AD, no one seemed to know who Sun Zi was.

Sun Zi had neither high political position nor influential social standing to merit a place in official history. He appeared to be merely a scholar with some Buddhist inclinations as is

evidenced in a problem mentioning the length of a *sutra*. The mention of *wei qi* (encirclement chess), and the taxation in terms of silk floss in other problems indicates the text of Sun Zi could not have been written earlier than the third century AD and later than the fifth century. Thus we assume he lived around AD 400.

Sun Zi Suan Jing is the earliest existing text to provide a description of the rod numerals and their operations. It also gives the names of large and small numbers, tables of measures for length, weight, and capacity, as well as densities for metals. The most famous problem is the oldest example of the remainder problem which reads as follows:

Now there are an unknown number of things. If we count by threes, there is a remainder 2; if we count by fives, there is a remainder 3; if we count by sevens, there is a remainder 2. Find the number of things.

The problem has since evolved into what is now known as the Chinese Remainder Problem. Written in modern form, the problem can be expressed thus:

$$N \equiv 2(\text{mod}3) \equiv 3(\text{mod}5) \equiv 2(\text{mod}7).$$

It appeared that Sun Zi's solution of the remainder problem had been extensively employed by the ancient astronomers to perform complicated computations of the calendar. By the thirteenth century, the problem was fully developed by ► [Qin Jiushao](#) with a sophisticated method of solution which also tackled the difficult case where the moduli were not relatively prime.

Sundials in China

Edoardo Proverbio

The measurement of time has a long history in China. Besides clepsydrae and water clocks, sundials and incense clocks were the only timekeepers employed in the epoch preceding the introduction of mechanical timepieces.

The earliest form of timekeeper used in China appears to be the sundial. Although the use of a simple vertical pole, employed to determine the epoch of solstices by measuring the length of the sun's shadow, appears to go back to Shang times (ca. 1500–1000 BCE), it is more difficult to establish the epoch in which the shadow of a simple style was used in China to measure time. Perhaps the most ancient reference is the one made by Joseph Needham et al., contained in the *Shi Ji* (Historical Record), which goes back to the beginning of the fifth century BCE. This reference, as well as those in subsequent epochs, makes no mention of the typology of these ancient sundials. Among later apparent references to the building of sundials of the equatorial type, there is the one contained in the *Sui Shu* (History of the Sui Dynasty), which refers to a “graduated sundial” the shadow of which reproduced the motion of the heavens. It was built by Ge Heng, a master of astronomical learning and instrument maker active in about the middle of the third century AD. One of the first descriptions of a Chinese equatorial sundial that has come down to us is contained in the *Duxing Zazhi* (Miscellaneous Records of the Lone Watcher) by Zeng Minxing (ca. AD 1176) in

which, among other references, it is stated that Zen Nanzhong, master of astronomy and a highly skilled instrument maker, who was active in Chiangsi province, invented and built many water clocks and sundials: “he also made two wooden dials with diagrams on them. One was set upon a wooden support for reading (the hours by) the sun’s shadow” (cited in Needham, Ling, & de Solla Price, 1986).

But the only extant ancient objects that appear to have been built and used as accurate timekeepers are the two so-called Han sundials, dated as former Han, perhaps going back to the second century BCE. These two objects have been interpreted in different ways. The most probable interpretation is, however, the one proposed by White and Milman in 1938. According to them the base-plate of these sundials was inclined in the equatorial plane, and the central gnomon was not a style but a rectangular plate connected with a perimetral T-shaped gnomon by a bronze bridge. Time would thus be shown by the position of the shadow of the peripheral gnomon in line with the bridge according to the graduation engraved on the face of the sundial. The season would be shown by the height of the shadow of the T-shaped gnomon on the central rectangular plate. Upon these ancient, supposedly equatorial solar timekeepers the graduations appear on one face only.

The most remote mention of the existence of Chinese equatorial sundials with surfaces graduated and a gnomon extending both above and below the equatorial plane plate appears to go back to the twelfth century. The *Duxing Zazhi*, mentioned above, reports the following passage: “So at Yunchang (Chiangsi province) he (Zeng Nanzhong) made a *Gui Yingtu* (diagram of the sun shadow) and constructed a sundial (*gui*). The dial was supported on posts so that it was high toward the south and low toward the north (i.e., in the plane of the equator). The gnomon pierced the dial at the center, one end pointing to the north pole and the other to the south pole. After the spring equinox, one had to look for the shadow on the side facing the north pole, and after the autumn equinox one found it on the other (the under) side” (Needham et al., 1986). Numerous

examples of late (Ming and Ching dynasties) Chinese equatorial sundials graduated on both sides have come down to us. The dials existing in the imperial palace at Beijing are of this kind.

Besides fixed equatorial sundials, two portable equatorial sundials made of lacquered wood, with inscriptions in red and black, or black only, were constructed in China, at least as far back as the Sung period (tenth to twelfth centuries). The largest production of these portable sundials appears to have been concentrated somewhere around the nineteenth century. Their construction is quite simple. They are generally composed of a rectangular piece of wood as a base plate with a compass needle having an azimuth graduation for meridian orientation set in it. A second, mobile lunette (the plate dial) is connected to the board at the middle.

The lunette is thus half the size of the base plate. The plate dial is graduated and may be raised or lowered to any desired angle so that the gnomon, fixed at right angles at the center of the graduation, may point at the pole whatever the latitude of the observer may be. The dial is then fixed in position by means of a ratchet prop. It is interesting to note that the latitude scale materialized by the position of the ratchet is given not in degrees or by the names of cities, but by the 24 fortnightly periods (*chi*) into which the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course) was subdivided in traditional Chinese astronomy. The hour lines of the equinoctial dial plate are also expressed in the so-called Chinese “double-hours” associated with the 12 ideograms of the duodenary cycle. In fact, despite their everyday, popular origin, these timekeepers seem to embody elements of the long tradition of Chinese geomancy or topomancy, divination by means of configurations of earth.

So we must believe that Chinese equinoctial sundials belong to the pure Chinese chronometric tradition, an interpretation that takes us back to the origin of the Chinese science known as *Feng shui* (geomancy, wind and water), based on the use of the geomantic compass, and of the ancient divinatory system based on the *Yijing* (I Ching, Book of Changes).

The first portable (and fixed?) horizontal solar time pieces were introduced into China starting from the end of the sixteenth century by Matteo Ricci and other Jesuit missionaries. Indeed, Father Ricci himself, in the preface to his memoirs, wrote: “As for their clocks, there are some which use water, and others the fire of certain perfumed fibers made all of the same size; besides this they make others with wheels which are moved by sand, but all of them are very imperfect. Of sundials they have only the equinoctial type, but do not know well how to adjust it for the position (i.e., the latitude) in which it is placed” (cited in Needham). The structure of these Chinese horizontal sundials which have come down to us is perfectly similar to that of the European “diptych” sundials, whose center of diffusion in Europe appears to have been Nuremberg in the late sixteenth century. Chinese horizontal sundials were not constructed before the end of the Ming dynasty (second half of the seventeenth century), and we have significant evidence showing that this kind of sundial was also employed more for geomantic purposes than as simple timekeepers.

Besides the two types of portable sundials so far mentioned, few specimens of a third kind of sundial, probably horizontal, consisting of a rectangular ivory plate, each one ruled for a different latitude, with hour and declination lines engraved, exist in China. The time of day and the period of the year were presumably indicated by the shadow of a style fitted into a central hole.

Unfortunately, given our still insufficient knowledge on the latter, as on other Chinese sundials previously discussed, it is often difficult to know exactly on what working principle they were based and the precise uses for which they were constructed and put to use. Even more uncertain is the epoch in which many portable Chinese sundials, still extant in museums and on exhibition, were built, where they were built, and by whom.

Sundials in Islam

Denis Savoie

Planetarium and Astronomy, Astrophysics
 Department of the Palais de la découverte,
 Observatoire de Paris, Syrte, Paris, France

During the seventh century, Arab and Persian scholars discovered Greek astronomy. Their expansion in the Greco-Roman world put them into contact with sundials and astrolabes, both of which share the same history. After a period of assimilation, these scholars brought back improvements to the gnomonic, and the sundial was put to the service of Islam. Islam changed the perception of sundials. These objects were not only rough indicators of the day as with the Romans; Arab Persian astronomers wanted those sundials to indicate accurately the times of prayer in a specific location. So it was out of the question to have merely empirical and approximate plots or to use a sundial calculated for another city. It needed accuracy, and this could

only be accomplished by using sophisticated mathematical and astronomical methods.

It is likely that the astronomical tables played a key role in this evolution. We know that many astronomers knew the work of the great astronomer of antiquity, Ptolemy (II century AD). In particular, he wrote a short treaty *On the analemma*, which can be considered as a treatise on descriptive geometry and should not be confused with the method described by Vitruvius in his *De architectura*, although the process has some similarities. The Ptolemy treatise contains no practical application for the construction of a sundial. We know from various sources, including the philosopher Proclus (410–485), that analemma (in astronomy, an analemma is a curve representing the changing angular offset of a celestial body from its mean position on the celestial sphere as viewed from another celestial body) dates back at least to the first century BC and at that time, Diodorus from Alexandria, a famous gnomonist, would have written about this method. The fact is that the analemma method was likely well known during ancient times, and it is then an important step in the calculation of sundials with trigonometric tools. Among others, the method is used by Thābit ibn Qurra (cf. below). The analemma method is essentially a trigonometric projection method: depending on the date, time, and latitude, one can calculate the position of the Sun, especially its horizontal coordinates (azimuth, altitude), project them onto a plane, and tabulate the basic parameters of a sundial (unequal length of time, length of the shadow, angle between the shadow direction and a geographic axis, solstices curves, etc.).

According to the *al-Fihrist* bibliography of al-Nadīm (d. 987), there is a long list of prestigious scholars who wrote in the first centuries of Islam about sundials and their purposes; this list includes Habash, Banu al-Sabbah al Farghānī, and al-Mahali. Al-Bīrūnī (973–1050), a scholar famous for the richness of his astronomical work, wrote a short study about the trajectory of the end of the shadow of a gnomon, using the tangent function. Much later, there are also numerous Mamluk authors who dealt with sundials.

Among them, there is al-Marrakushi who worked in Cairo in the thirteenth century with his famous *Treaty of astronomical instruments*, a major work of the Arab gnomonic. There are also the gnomonic tables of his contemporaneous al-Maqsi or Ibn al-Sarraj, one of the greatest specialists of these time measurement instruments. In their writings, these authors discuss a wide variety of dials: horizontal, vertical, inclined, cylindrical, and conical. Many of these treatises are in libraries waiting to be studied one day.

Arab Persian gnomonic also produced portable sundials, one of the most well known being the copper specimen that belonged to warlord Syrian Nūreddin (1117–1174), called “locust’s leg.” Like most portable dials belonging to the cylinder height type, known since Greco-Roman antiquity, the principle is to determine the time from the height of the Sun above the horizon during the day. The use of these dials to determine prayer times was mostly anecdotal.

Early in history, the mathematical study of sundials was a well-established discipline whose practitioners were marked out by a dedicated word (*Ashab al-azlal* in the words of Ibn al-Haytham) and recognized as craftsmen. So we have from the ninth century, tables and books dealing with the calculation of dials, like the ones of Baghdad astronomers al-Khwārizmī (780? -850?) and Thābit ibn Qurra (836–901). The work of the latter, *Works of astronomy*, contains two important chapters on gnomonic that make it one of the oldest treatises in Arabic on the subject. Thābit ibn Qurra considers plane dials with a perpendicular gnomon and looks for plotting hour lines on their surface depending on time, date, and place. He looks at the classification of meridian planes, the horizon and the first vertical – as did Ptolemy – but also adds other cases and finally considers one of the inclined and declining dials, indicating that it works as a horizontal dial in another place (equivalent latitude theory).

Everything indicates that one has to wait until Ibrāhīm ibn Sinān (909–946) for the first substantial writing about sundials with his treatise *On shadows instruments*. Ibn Sinān there develops

a unified theory of these instruments, based on strong geometric bases. In particular, he underlined the problem of uneven hour lines that are not straight lines – as already written by his grandfather Thābit ibn Qurra – but curves. In the first centuries of Islam, one drew unequal hour sundials (as on antique Greco-Roman dials) which resulted from the division by 12 of the time interval between sunrise and sunset. These hours have varying durations that depend on time and place. Equinoctial hours, lasting 60 min, were the only ones used by astronomers in their calculations and were later superseded by uneven hour sundials. Thābit ibn Qurra, in his book, gave the possibility to draw equinoctial hours. The most famous Arab Persian dial with equinoctial hours is the horizontal sundial found in the Umayyad mosque in Damascus, built by astronomer Ibn al-Shāṭir around

1371–1372. It has two features: first, it is a masterpiece in the complexity and comprehensiveness of its drawings. But more importantly, it has a polar gnomon that is seldom seen in an Islamic dial; this was so far the oldest known of its kind. Does this mean that dial with polar gnomon are an Arab Persian invention? Everything leads us to believe it.

The project of Ibn Sinān was resumed by Ibn Haytham (965–1039), who wrote two books about sundials. One was dedicated to mathematicians, entitled *On the hour lines*, and the other was dedicated to sundial craftsmen and entitled *On horizontal sundials*. In the first book, Ibn Haytham went back to the problem of temporary hour lines geometry. Ibn Haytham, as did Ibn Sinān, wrote application books so that craftsmen would be sufficiently enlightened to build sundials, since that is the purpose of his second book

Sundials in Islam, Fig. 1 Sundial of the Ibn Tulun Mosque in Cairo. Very faithful reproduction of a beautiful sundial disappeared, published in the *Description de l'Egypte* prepared by scholars who accompanied Bonaparte in Egypt. This is a horizontal sundial cut into two parts nested. Dated from the late thirteenth century, it indicated unequal hours represented by the inclined lines, framed by two arcs of hyperbolas solstices. The entire route is cut by the right of the equinoxes. Between the 9th and the 10th hour is the curve of the *Asr* prayer. Cadran solaire de la mosquée d'Ibn Tulun du Caire. Reproduction

très fidèle d'un magnifique cadran solaire disparu, parue dans la *Description de l'Egypte* préparée par les savants qui accompagnaient Bonaparte en Egypte. Il s'agit d'un cadran solaire horizontal coupé en deux parties imbriquées. Daté de la fin du XIII^e siècle, il indiquait les heures inégales représentées par les droites inclinées, encadrées par les deux arcs d'hyperboles des solstices. L'ensemble du tracé est coupé par la droite des équinoxes. Entre la 9^e et la 10^e heure se trouve la courbe de la prière *asr*

Sundials in Islam, Fig. 2 Sundial in the Cairo Citadel (Egypt). Remarkable multiple sundial, vertical declining southwest dated eighteenth century. There are five sundials each operating with their own gnomon. The sundial indicates the equinoctial hours, *Asr*, *Zuhr*, and *Maghrib* prayers, and has curves for *Isha* and *Fajr* twilights.

Remarquable cadran solaire multiple, vertical déclinant sud-ouest, daté du XVIII^e siècle. On y trouve five cadrans solaires fonctionnant chacun avec leur propre gnomon. Le cadran indique les heures équinoxiales, les heures de prière de *asr*, *zuhr*, *maghrib* et comporte les courbes pour les crépuscules de *isha* et *fajr*.

on horizontal sundials where he explains in particular how astrolabes were used to draw sundials.

It is believed that thousands of dials were built since the ninth century in the Islamic world, but many have disappeared (like the one of the Ibn Tulun Mosque in Cairo, which dates from 1296 and which is only known thanks to an etching) or are not inventoried; Figs. 1 and 2.

This abundance is a major feature of the Arab-Islamic sundial which demonstrates its strong links with religion, a link that comes from the definition in Islam of prayer time in terms of variation in the length of shadow. Thus, there was a need to include on sundials some *asr* or dusk curves, but also to draw the equivalent italic hours to know how much time is left before the Sun sets. The first *asr* curves seem to appear on Arab dials in the eleventh century (Vth Hegira). The *asr* is the moment when the shadow of a gnomon of length a is equal to its meridian length increased by its own length; by defining φ the latitude and δ the declination of the Sun,

this corresponds to a height h of the Sun given by $\cotan h = 1 + \tan(\varphi - \delta)$. One finds, for instance, in the treatise of al-Marrakushi lots of explanations and tables to plot these curves.

The expansion of the gnomonic Arab Persian in Europe via the Maghreb resulted in a sort of revival of sundials manufacture between the thirteenth and fourteenth centuries in Andalusia as reflected, for example, by the treatise of Ibn al-Raqqūām which dates from the fourteenth century and uses the analemma methods.

The architecture during the Mamluk and Ottoman periods has many sundials adorning the walls and courtyards of mosques, a tradition that lasted until the end of the nineteenth century. Many of these prayer dials are works of prestige, as reflected by their smart engraving and their geometry and ornament. A very special feature of these dials is manifold: it is almost a gnomonic block where there are several dials and therefore several gnomons (one that indicates *zuhr*, one for *asr*, one for *maghrib*, one for the time remaining before the dusk prayers). Their relative disposal

obeys criteria that combine aesthetics and astronomical necessity. Their fine sculpture, the calligraphy of embossed Arabic letters, and their mathematical accuracy make these sundials incomparable masterpieces that must be preserved.

Surgery in Ancient Egypt

Hedvig Györy

In ancient Egypt, because a majority of the population had to endure hard physical toil, bone abnormalities such as arthritis, inflammation of the joints, bone attrition, kyphosis, osteoarthritis, or tuberculosis were a common occurrence. None of these conditions were, however, considered surgical cases. The surgical repertory was limited. Both physical remains and written sources support the notion that operations were sporadic and minor, and that the emphasis was on physical treatment of fractures or dislocations, with a few cases of incisions or cuts into certain regions of the body. There were also various external organic alterations like abscesses, boils, fistulas, hemorrhoids, ulcers, and some superficial growths. Malfunctions of the nose, ear, and teeth were treated in this manner only occasionally. In treatment, the anatomical knowledge applied was taken from earlier medical observations and theories, not from the science of mummification. Good examples of this are the mummies examined by Regöly-Mérey: in 17 cases, the brain was removed transnasally, in 8 cases the frontal and facial sinuses were removed, and in 5 cases the pterygoid sinus had been opened up. Thus, these sinuses had to be penetrated with a hook, but none of these sinuses is ever mentioned in the medical treatises.

Sources

If we consider surgery (from the Greek *cheirurgia* meaning "hand work") as a medical specialty that treats illness by operative manual and instruments, its most important characteristic is wound management. Looking at the ancient Egyptian word for physician, we find the *swnw* written with an arrow-shaped hieroglyph. It has been suggested that the arrow shape has its origin in the fact that the primary occupation of

physicians was treating injuries received in combat. Physicians were experienced in removing arrows, similar to the god Thot, or perhaps they used arrowheads to lance abscesses. But a very limited number of pictures and only relatively few passages in the medical papyri describe surgical wound management in ancient Egypt. The Ebers papyrus (855–77), Hearst papyrus (217–27, 245, 260), London papyrus (29, 43–4) and, the most extensive, a complete scroll – the Edwin Smith papyrus – all contain descriptions.

References to surgical cases interspersed among prescriptions in the above-mentioned first 3 scrolls suggest that surgery was considered as part of any healer's art. This conjecture seems to be relevant for all three types of healers – physicians, priests, and magicians – since they are all named in the Smith papyrus when speaking about the examination of the patient's pulse. Ancient Egypt was, however, very advanced in medical specialisation and thus there might be a distinction among physicians dealing predominantly with surgical cases – as the priests of Sachmet are believed to have been specially trained surgeons (even for animals). Early distinction between surgery and pharmaceutical medicine is the most pronounced when looking at treatments of internal versus external cases: practically all the operations are directed at repairing external parts of the body, mostly for already existing damages.

The Smith papyrus was a manual for use by an army surgeon or practitioner for treating accidents or for teaching purposes. It is essentially a treatise on wounds, internal pathology, and bone surgery with meticulous clinical observations. It lists 48 cases of injuries and lesions along with the appropriate treatments. It follows the *a capite ad calces* (from the head to the calves) method, common in Western medicine until the Middle Ages. It starts with skull lesions, continues with caudal lying injuries on the head, in the neck, the clavicle, the humerus, the sternum, and the shoulders, and finishes with a description of the region of the spinal column, where it stops abruptly in the middle of the case of the fourth thoracic vertebra. But it was not the only ancient book in this field. It mentions, for instance, in case 5,

another one, with the title “On Wounds,” the structure of which could be similar to that of the Smith papyrus. It contained case studies for medical treatment with explanatory glosses, but it might also have been a teaching book for anatomical and physiological features, since it is quoted as an explanation of a physical condition that results when the skull is splintered. The Smith papyrus is matter of fact and sober and would even fulfil today's requirements. The inductive process that deals with these cases is the oldest known example.

Case Study

The surgeon elicited information by questioning the patient or directing him to attempt certain movements or postures. His own ocular, olfactory, and tactile observations were then added. For case studies, conditions were closely observed, symptoms described and effective treatments noted in a remarkably scientific manner. These procedures were, however, accompanied by an equally important religious/magical rite, known from different sources. For instance, the ancient Egyptians believed that the illness passed into the bandage (called *trap* in Eb. 2) and thus, with the removal of the bandage, the illness was also thought to be removed.

Wound Repair

The ancient Egyptians regarded symptoms of infection as part of the recovery process. They also realised pain, but interestingly, they never mention anaesthesia for use in surgical interventions, although they had means for it. The silence can be the consequence of both its non-existing (e.g., holding the patient down) or having methods which were trivial – e.g., being drunken. Its only possible occurrence is an Old Kingdom circumcision scene (see a comprehensive description in the article ► [Wound Healing in Ancient Egypt](#)).

Ancient practitioners were more deeply concerned with arresting haemorrhages, since

the *mtw* (Eb. 871), tumours (Eb. 875), and wounds were susceptible to bleeding. The main wound repairing methods were bandaging with an ointment or poultice, scorching (Eb. 872, 876) and surgery. In doubtful cases, enforced bedrest and normal diet were often recommended to the patient until he reached the decisive moment when the healer could give either a positive or negative prognosis.

In many cases, as mentioned in Eb. 510–42, injury treatment was restricted to various medicaments. For instance, a typical first-day treatment was to put raw meat on the fresh wound, which induced haemostasis. A suppurating wound was likely to be cured by honey (Eb. 513), which is hygroscopic (capable of easily absorbing moisture) and stimulates the production of white blood cells, or by astringent herbs such as acacia leaves (Eb. 527). They also used wound dressings which combined, for example, honey and *snt* (incense, Eb. 515) or wax and *mrḥ.t* (grease/oil, Eb. 518), providing protection and promoting healing. Discharge and suppuration might also be treated by fat, ground peas and fermented barley bread, causing an antiseptic and hygroscopic effect (Eb. 522) – and, in the case of bread, possibly yielding penicillin. These last materials were given in sequence: (1) ox fat on the first day to induce the wound to become foul; (2) barley bread for drying it; then (3) several other things alone or in combination on the following 4 days. Thorn pricks (Eb. 726–32) were treated with poultices or ointments. Similar treatments could also certainly be applied to artificial wounds.

We do not know the criteria the surgeon used to determine the place for an operation, i.e., *d w-^c* – “knife-treatment.” Neither is a special operating theatre mentioned thus far, which may mean that the operation was performed at the patient’s home.

Main Surgical Categories

Trauma (By Accident or Combat)

Based on many relatively good healing settings, we can assume that ancient Egyptian bone setting

was advanced. Among the skeletal remains from ancient Egypt, there are innumerable completely healed limbs with good realignment of the bone, but most other bone settings often show gross shortening and misalignment. Since fractures of the femoral bones often healed without complication, it may indicate, on the one hand, that the virulence and incidence of pyogenic pathogens was lower than they are today, although their existence is proved by the frequency of osteomyelitis. On the other hand, based on the skeletal remains of pyramid workers and other Egyptians, it is obvious that fractured limbs were splinted using an advanced technique suitable even by modern standards. Cleverly, if only one of the bones of the lower leg or forearm was broken, the remaining intact bone could serve as a splint for the broken one, and healing was satisfactory. In instances where the damage was so severe, however, amputation was an alternative course of action.

Representations of injuries are relatively infrequent. Two of them are accurate enough to mention: the accidents drawn on the wall of the tomb of Ipui which happened in the joiner’s shop and the pictures of the battle of Qades in various temples. Moreover, medical papyri, especially the Edwin Smith papyrus, are very accurate and detailed in the description of various types of injuries and their treatments. They tell us that the healer was able to characterise the most important types of injuries, impressive even by today’s standards. They differentiated among various types of swellings, fractures, and joint injuries.

Besides the superficial wound (*wbnw*), they cured the *wbnw kft* – a deep gaping wound, as, for instance, in Sm. 28, where the most important clinical sign for an open oesophagus, drinking water regurgitating through the wound, is mentioned. The axillary could also be open (Sm. 47). The most common complaints, swelling and fever, indicate that wounds were often infected. In the special case of perforation, the word *thm* is used. Wounds were often surgically treated by suturing with *jdr* stitching (Sm. 3, 10, 14, 23, 26, 28, 47) and/or bandaging (Sm. 2, 9, 10, 27, 47). Basic medicaments for curing were honey

and fresh animal meat, but, in specific cases, many other ointments and poultices were also applied (Eb. 510–42). Sometimes a sequential approach was used (Eb. 522).

In the case of fractures, the ancient Egyptians differentiated a simple closed *sd*-fracture, where the bone is broken in two, from a commuted compound or impacted *pšn*-fracture, where the bone is broken in several places. As a diagnostic clinical sign of fracture, *nhbhb*, meaning, in all probability, “crepitation,” is mentioned. The standard procedure for the reduction of fracture was traction (Sm. 12, 35, 36). And, indeed, many humeri were found in graves still set in splints. The first procedure was, after realigning the broken limb, to set it either with a splint wrapped in bandages, or encased in a healing poultice cast that could be made of various (often unidentified) materials; as, for instance (just to mention some known substances), cow’s milk mixed with barley (H 219) or acacia leaves bound together using gum and water (H 223). For reducing a fracture of the clavicle (Sm. 35), the ancient Egyptians also used a method still applied, but first described among Greek physicians by Hippocrates, by stretching the patient “on his back with a folded cloth between the shoulder blades” and pulling “on his two shoulders until the fracture falls into position.” Among the neurological complications, as in the case of an impacted fracture of the cervical vertebrae (Sm. 33), aphasia, unconsciousness and tetraplegia, are mentioned.

Concerning injuries to joints, dislocations (*wnh*) and sprains (*nrw.t*) were treated. In the tomb of Ipuï in Deir el-Medineh, there is a picture of industrial accidents. Among them the use of Kocher’s method for dislocated shoulders can be clearly discerned (For information on Kocher’s method, see <http://www.tki.unibe.ch/theodor.htm>). Other methods are described in the Smith papyrus, e.g., treatment for the dislocation of a jaw (Sm. 25). For neurological complications resulting from the dislocation of a cervical vertebra the inability to move the limbs, priapism, urinary incontinence, and intestinal dilatation with gas secondary to paralytic ileus are given (Sm. 31). In another case, a positive Lasague sign is described, i.e., pain due to a sprain of the

vertebral column when the legs are extended (Sm. 48), which indicates a prolapsed lumbar intervertebral disc with nerve involvement.

Based on two ivory slabs bearing the names of kings Aha and Djer (both first Dynasty), some specialists assume the use of tracheotomy, a procedure that opens the airways to maintain breathing. The slabs represent a man kneeling, with his hands tied behind his back and with a pointed instrument directed at his throat. As the man holding the tool is seated, the scene is unlikely to be a battle scene, and, since the process is not repeated in later representations and the situation is not described in later medical texts, an interpretation of ritual execution (?) is also possible.

Skull Surgery and Trepanation

According to the Edwin Smith papyrus, the ancient Egyptians recognised brain disorders and performed skull repair. They were also the first in the history of medicine to identify the inner parts of the cranium, as *tpw*, the falx cerebri, or protruding dura mater (The dura mater is the tough fibrous membrane covering the brain and the spinal cord and lining the inner surface of the skull. It is the outermost of the three meninges that surround the brain and spinal cord) – based on the description, or as *ntnt*, the meninges (Sm. 6). They also provided vivid descriptions of the brain and cerebrospinal fluid.

Parallel to the development of weapons, the number of head injuries increased (Fig. 1), thus causing a discussion of the many cranial injuries in the Smith surgical treatise. The dominant factor in healing, however, seems to be the *vis mediatric naturae*, the expectant healing power of nature. This is also manifest by the signs of treatment on heads with cranial injuries found by Elliot Smith, Wood Jones, Courville, and, recently, Nerlich, which are far from adequate if any medical treatment’s sign is present. A successfully recovered head injury to Amenemhab, who saved Thutmosis III from an attacking elephant in Nij/Mitanni, is known from literary tradition, while Breasted published the results of a palaeopathological examination of the mummy of General Ossi-numph-neferu, with a 7.5-cm long, caved-in, but completely

Surgery in Ancient Egypt, Fig. 1 Head of Seqenenre Taa II, showing multiple injuries acquired in battle (Source: LECA, A–P. *La médecine égyptienne au temps des pharaons*, Paris 1971, Fig. 94, p. 372)

healed, left side frontotemporal bone wound. This recovery is a great achievement even by current standards of surgical knowledge.

Craniotomies were well known in ancient Egyptian practice. A special treatment was trepanation, which is essentially making a hole in the skull without damaging the cerebral membrane. Today, only a few unquestionable cases are known of perfect healing at the edges that testify to a longer life, and, based on its absence in the Smith papyrus, it was certainly not regarded at that time as a medical treatment. But many other interventions were considered surgical, and some of them are given in the Smith papyrus with a modern scientific approach of clarity and diagnostic accuracy.

The first 8 cases in the Smith papyrus deal with various injuries of the skull (for details, see *Wound Healing in Ancient Egypt*). Pathological descriptions give clues to the identification of symptoms such as meningeal irritation, cerebral prolapse, nuchal rigidity (stiff neck), trismus

(lockjaw), tetanus, contracoup (brain injury), or hemiplegia (weakness on one side of the body). Complex case studies indicate a basic medical understanding of the function of the brain. They also knew their limits very well – when a cure was hopeless, palliative treatment was undertaken.

Plastic and Prosthetic Surgery

In some cases, wound treatment meant not only the healing of the wound but also the reconstruction of an earlier structure. Typical examples are Sm. 11–2 cases with plastic surgery of the nose. Besides the treatment of the fractured bone, by the usual means of application of *mrh.t* (oil/grease), honey and fibres, two fabric *ads* soaked into *mrh.t* were introduced into the cavity and applied to the bridge of the nose. Then the nose was bandaged above two linen pads, which protected the nostrils from distortion. The same reasoning led to the fixing of the auricle by means of a small cushion after the suturing of the ear in Sm. 23. Following local applications, a supportive bandage was also recommended for an ear wound in Eb. 766.

A surprising innovation in ancient Egyptian medicine was the use of prostheses (artificial limbs). We know that long ago there was a post-mortem nose prosthesis, for instance, on a Ptolemaic period Gamhud mummy, clearly shown by the fact that the straps are above the mouth and the chin, which then go to the base of the cranium where they are tied in a knot. Consequently, for a long time it was thought that restorative surgery was only used by embalmers to maintain physical integrity for eternal life.

There were doubts about the earliest prosthetic contrivance, two 4th Dynasty teeth fixed together by a golden wire, found in the Gisa cemetery. After a long debate, the conclusion seems to be that it was made for a dead person (The next artificial teeth, the holding of a maxillary bridge by a silver wire, were found in the Ptolemaic period.).

A prosthetic big toe, however, recently discovered in Thebes on a mummy of the 21st/22nd Dynasty in Tomb 95, was certainly made for a living person (Fig. 2). The linen-wrapped

Surgery in Ancient Egypt, Fig. 2 Hook and needle in the Egyptian collection of the museum of fine arts, Budapest

foot and leg show evidence that the amputation was cleaned and prepared for this device. The amputation is completely healed, and the wooden prosthesis, made up of three separate components, is worn on the sole, which indicates that the owner lived long using the prosthesis after the accident (As a reason for amputation of the toe, ischaemic gangrene has been suggested.). Another (in this case cartonnage (Cartonnage was papyrus or linen soaked in plaster, shaped around a body. It was used for mummy masks and coffins)) toe prosthesis from Thebes around the same period, kept in the British Museum, was applied also to a living person; again, wear and subsequent refurbishment can be observed.

Pathological Extensions

Pathologies were well differentiated: several sorts of tumours, abscesses, cysts, swellings, boils, etc. (*hn̄hn.t.t*, *sft*, *nw.t*, *šfw.t*, *hsd*, *tw.w*, *bsj*, *hm*, *sh*, *bnw.t*, *wnm-snf*) are mentioned in the

Ebers, Hearst and Berlin papyri, with very brief medical instructions. These might have been treated in the following ways:

- Medicaments, for instance, Eb. 51–581, 855–62, H 41, 132–33, 136–39, Bln. 52–7 or the last step in Eb. 877;
- ... treat it similar to the treatment of the *s-hmm* “(firebolt?-man)” for scorching the skin-like flesh-protrusion in Eb. 863 or the (umbilical or epigastric?) hernia in Eb. 864.
- *thn* – piercing with the *Hmm* as in Eb. 865 for the ascites (fluid in the abdomen);
- *dw*-“knife-treatment,” meaning, probably, excision, as in Eb. 866 for a vascular tumour (haemangioma?), Eb. 867 for a presumably subcutaneous lipoma; Eb. 868 for a possible sebaceous tumour with metastasis (*tnts*); Eb. 869 for an abscess; Eb. 870 for a swelling, the identification of which has several possibilities, such as a dermoid cyst lined with skin appendices, pilonidal sinus located in the mid-line or sebaceous cyst of the scalp, as, for instance, atheroma; Eb. 871 for an abscess in the axillary lymph glands;
- *dw*-“knife-treatment” with heated (*sšmm*) knife as in Eb. 872 for a probable haemangioma;
- Either excision or scorching according to the state of the tumour, as in the first 2 cases in Eb. 876; or
- The tumour was left untreated, as Eb. 874. This might have been leprosy, or in Eb. 873, a possible cavernous haemangioma, or a twisted vascular swelling forming knot (in this case, however, the *mtw* should be straightened). The first 2 steps in Eb. 877 are still unidentified although cancer, cutaneous leprosy, bubonic plague, or neurofibromatosis have already been suggested. In the last step in Eb. 876, the ball-shaped extensions have tentatively been identified by Regöly-Mérei as varicosities.

In all the above cases, procedures are not described and thus nothing definite is known. The only complex and detailed surgical process is given in the Ebers papyrus (Eb. 875) – with

various knife and forceps devices – and is, in all probability, the month-long treatment for dracunculiasis (Dranunculiasis, also known as Guinea worm disease, is a painful and debilitating infestation contracted by drinking stagnant water contaminated with Guinea worm larvae that can mature inside a human's abdomen until the worm emerges through a painful blister in the person's skin) (which may be the origin of the caduceus, the medical emblem with snakes), and thus a very atypical surgical invention.

Circumcision

Herodotos (II.37) wrote: "They practice circumcision for cleanliness, for they set cleanliness above seemliness," but we find no mention of it in any medical or iatromagical text, and its two representations hint at a sort of feast for ritual initiation, probably for procreative purposes. Conceivably, the traditional practitioners had religious ties, and were most probably priests, since the fulfilling of the cleanliness doctrine was the most important one for temple workers. Based on a representation of the tomb of Ankhmahor, it was performed by a scalpel or some sort of blade. Following the Ptolemaic rule, physicians could do it, too, as later the use of Roman instruments, such as forceps and scalpels, was common in this field.

There is only one mention in the First Intermediate Period stele of Uha of circumcision being performed on females in Pharaonic times, where a crowd of men and women are participating in the cultic rites that accompanied the procedure. It seems, based on this mention of a communal feast, that female circumcision was also primarily ritualistic and it has been hypothesised that it was also associated with temple activities, although I think it was primarily the same sort of fertility rite as that for men – at least the above communal feast hints at it. We do not know, however, how popular the act was, or when, how or why it came into existence. In any event, it must have lost its festive side, as it never appeared again as a public act. It must not have been obligatory, since virgins were also referred to as *m'.t*—"uncircumcised," from the Middle Kingdom on. Based on the state of preservation

of the pubic area on mummies, the fulfilment or non-fulfilment of the act of circumcision cannot be definitively determined. According to written sources, however, in Graeco-Roman times, nymphotomy/clitoridectomy seems to have been a widespread custom in Egypt. Soranus (second century B.C.E.) first recommended the process for girls with excessively large clitorises. He gave as the reason for the operation the shame that results from its erection and the girl's excessive desire for sexual indulgence caused by the abnormality. According to Aetios, who used Hellenistic and Roman imperial sources, the ancient Egyptians excised the clitoris especially around the time when the girl was about to be married.

Burns

In the Ebers papyrus, there is a complete book on wounds originating from burns: 482–509. No. 482 lists a sequence of remedies which, it says, should be applied consecutively. In other cases, remedies applying an ointment or a bandage are the same during the entire treatment. Similar to cases in the London papyrus (15–21, 46–8, 53–61) and also among the Ebers papyrus prescriptions (482–500), magic spells had to be cast, referring to Horus having been burnt in the desert. According to the incantation of Eb. 499 which had to be recited with mother's milk, Isis used "water in her mouth" and "Nile springing between her thighs." Mother's milk, gum, and ram-fur (having a high cholesterol content) were put on the burnt wound. As for surgical procedures, Eb. 504 speaks about opening a blister with a sharp thorn, and Eb. 501 mentions an incision on a blister sandwiched between two prescriptions, but, as usual, without any details.

Various Types of Bites

According to the Brooklyn herpetological papyrus, snakes and the effect of their bites were accurately identified, and their bites treated with rational medical care. The treatments comprised the application of a bandage with salt and natron, (Natron was a salt (sodium carbonate and sodium bicarbonate) that was used in the mummification process to dry out the body of the deceased in order to assist in its preservation) both being

antiagglutinant (An antiagglutinin is a substance that makes particles (such as bacteria or cells) stick together to form a clump or a mass) and antihaemolytic (Haemolysis is alteration, dissolution, or destruction of red blood cells in such a manner that hemoglobin is liberated into the medium in which the cells are suspended, e.g., by specific complement-fixing antibodies, toxins, various chemical agents, tonicity, or alteration of temperature) thus impeding the absorption of the venom; drinking of emetic remedies with various material to get rid of venom by vomiting; fumigation as adjuvant; magical spells for general and specific divine help and/or the *ḏw*-^c “knife-treatment” and the *tštš*-incisions in the swelling.

Other types of bites, such as those from crocodiles (Eb. 436, H 239–40, 243), lions (H 244) and humans (Eb. 432–35, H 21), were treated like any other wound, preferably by applying fresh meat on the first day and, subsequently, honey, wax, and *mrḥ.t* as in Eb. 435 or by using other herbal remedies, occasionally with the addition of some animal ingredients.

Dental Surgery

Dentistry is among the earliest medical fields in ancient Egypt. Even the first known Egyptian physician, Hesira, was a dentist. A wide range of dental treatments is listed in the medical papyri, such as filling teeth, treating gums or abscesses, and reducing halitosis. But no surgical inventions are mentioned, although an alveolar process using piercing to drain an abscess under the first molar has already been found in a mandible from the fourth Dynasty. Neither is tooth extraction described, and, based on the many abscesses and cysts found on mummies, was rarely, if ever, practiced.

Surgical Devices

There were several specialised surgical devices (Fig. 3), as various types of knives for cutting tumours, needles for suturing, several types of spatulas for applying the medicaments, “fire drills,” and metal cauteries for operations and disinfection. They made splints and bandages

Surgery in Ancient Egypt, Fig. 3 Prosthetic big toe from Thebes

very skilfully, having specialised books on this topic – primarily for the embalmers, but as the Smith papyrus says, physicians used them as well. Hooks and forceps were probably also often common with the embalmers, although such devices as the small leather forceps, called *hnw(h)* must have been a surgical speciality. They also used several natural objects, such as acacia thorns for cutting up blisters and the bulrush knife for removing elastic foreign bodies. Seemingly they were adapted to the various functions surgeons had to accomplish during the various stages of different types of operations. Parts of the instruments were also used for cosmetics; ointments were made and applied the same way for both purposes. The execution could have been of different quality according to the demand, although they are mostly primitive. The problem is, however, that only a few surgical devices survived (often unprovenanced), and representations are missing – the Kom Ombo temple relief originates from the Roman times, so ancient Egyptian and Roman medical instruments are

already mixed. We do not have detailed knowledge of pharaonic surgical devices.

Surgeons

The practitioners of all the above procedures might have been very different people. Surgeons, i.e., medical practitioners specializing in surgery, seem not to have existed in the modern sense during Pharaonic times. Operations were performed by the practitioners, dentists, priests, or magicians. For combat/battle injuries there was a military physician, problems with teeth were handled by a dentist, complications of the ear or nose were treated by the specialist or by a general practitioner. For bites, the *hꜣp Srdt*, the “controller of Selket” was responsible, while circumcision might be the task of the *kz*-priests.

Surgical procedures are, however, attributed by Egyptologists most often to the priests of the lioness goddess, Sechmet, who were veterinarians (as the ancient Egyptian said: “one who knows bull”) too. Aha-nakht, a colleague of the *swnw* Hery-shef-nakht, of the Middle Kingdom introduced his picture in his Hatnub graffito with the words: “The scribe of the hall of judgement, Aha-nakht. I am a wab priest of Sekhmet, capable and skilled of his brotherhood, who places hand on a man when he knows it (i.e., the illness), skilled in examining strongly and one who knows bulls,” thus attesting to a medical connection for these priests. The *dw*-‘- knife-treatment, however, is said in Eb. 501 to belong only to the *swnw* physician as the secret knowledge of the beating of the heart belongs as well to the *swnw* as to the *wꜣb* priest of Sekhmet and to the magician.

The account given in this article represents the state of surgery during the New and, probably, the Middle Kingdom periods in Egypt, since our sources date mainly from these periods, but it was probably not very different during the preceding and following periods. Wound management has always been an important part of human life and thus probably the first medical books (see ► [Medicine in Ancient Egypt](#), especially the note on Egyptian Medical Papyri) already contained

appropriate instructions. It is unknown, however, how much they differed from the Middle Kingdom methods, where the latest research places the original of the texts of the Smith papyrus. The concept was probably the same, as we find in the few New Kingdom Berlin papyrus prescriptions for bite and the very complex 30th Dynasty (?) Brooklyn Museum herpetological papyrus. A great transformation seems to have taken place only later, with the gradual fusion with Greek medicine via the Alexandria School.

Surgery would be used in ancient Egypt only if a cure could not be achieved by means of prescriptions or other methods, and if the patient was not in a terminal condition, when only palliative steps were taken. And, indeed, it was often the best solution as success would certainly not be guaranteed even in standard operations, in spite of the relatively advanced methods, due not only to imperfect anatomical knowledge, but also to the lack of both effective anaesthetics and of antiseptics and the low level of hygiene, which could lead to septicaemia.

Surgery in Ancient India

Anek R. Sankhyan

Palaeo Research Society, Ghumarwin, India

The *Rgveda*, the earliest account of ancient Indian civilization, makes mention of the Ashwini Kumaras, known as *dev vaidya* (doctors of the gods). They were the chief surgeons of the Vedic period who had performed rare legendary surgical operations. Without entering into the complicated references of ancient texts on this, the latest simpler version is provided by Ahuja and Mishra (2014) in a brief overview mentioning the legendary surgeons and ancient Indian Ayurvedic surgical practices.

The *Rgveda* says that the Ashwini Kumaras performed the first plastic surgery to rejoin the head and trunk of saint Chyavana when Dakshya cut his head. Their other classic works include: an eye operation of Reejashva, the implantation of the teeth of Phushna in his toothless mouth, the transplant of the head of a baby elephant on

Ganesha whose head was cut by Lord Shiva in a rage of disobedience, rejoining the head of Lord Brahma and saint Dadhichi severed by demon Bhairava, and transplant of the head of a horse on the body of *Dadhyancha* preserved through *madhu vidya* (honey method). In addition, they transplanted an iron leg on Bispala, the wife of king Khela, who had lost her leg in war; they also operated and repaired the excised head of Yagyana by Rudra. In other words and on the face of it, the Ashwini Kumaras were doing both homo- and heterotransplantations at the very ancient time of *Rgveda* 5,000 years ago!

Such miraculous magical surgical skills of the *Rgvedic* time may seem mere legends or mystery to modern medical science and we may not even believe that. Nevertheless, they do reflect some special surgical skills which laid down the foundation of the *Āyurveda* – the fifth Indian Veda – the classical medical system of India.

However, the realistic and systematic earliest compendium of medical science of ancient India compiled by Caraka is known as *Carakasamhitā*. It describes the works of ancient medical practitioners, like Acharya Ātreya and Acharya Agniveśa of 800 BC, and contains the *Principles of Āyurveda* that remained like a standard textbook of *Āyurveda* almost for 2,000 years. They were followed by Acharya Suśruta around 600 BC, who was a specialist in cosmetic, plastic, and dental surgery, called *Sandhan Karma*. He treated numerous cases of *Nasa Sandhan* (rhinoplasty), *Oshtha Sandhan* (lobuloplasty), and *Karna Sandhan* (otoplasty). He is therefore known as the “Father of Surgery,” and his works are compiled in the *Suśrutasamhitā*, which describes over 120 surgical instruments and 300 surgical procedures and classifies human surgery into eight categories. He described 60 types of *Śāsti-Upakrama* (treatments for wounds).

Considering the great surgical skills achieved by ancient Indian surgeons, right from the Ashwini Kumaras, Chyavana, Dhanvantri through Ātreya, Agniveśa, and Suśruta, brain surgery (craniotomy) was likely practiced in a more sophisticated way which had very much improved upon the protohistoric trepanation then in vogue elsewhere in the world. It is quite

likely that the trepanation gave way to early ancient Indian surgical practices which eventually developed into the modern scientific surgical skills of the Āyurveda much before they spread elsewhere and got assimilated with similar indigenous traditions, such as Greek, Unani, or Hikmat.

Trepanation

Ancient Indian surgical knowledge is expected to have evolved quite early from the Bronze Age and Neolithic traditions of trepanation then performed by flint, copper, and bronze instruments. The advancement came with mastery of iron smelting that produced not only iron weaponry but also various kinds of surgical instruments for craniotomy. At the same time, there were refinement and new discoveries of better and safer anesthetics and pain-killers to use during surgery.

Of course, trepanation, also called trephination or trephining, in which the brain was exposed by drilling or cutting through the skull vault, was a very primitive surgical practice common in the Neolithic, Chalcolithic, and Bronze Ages. It was used both for medical and magico-religious reasons, done either on the living person (antemortem) or just after death (postmortem). We view such surgical intervention on the human brain case frightening even today with modern technology, so we can imagine how terrifying trepanation was for the patient when done by ancient surgeons as early as 5,000 years ago with archaic implements like flint knives, shell scrapers, and drills using crude anesthetics and pain-killers! The survival of the patient depended much on the ability of the medical practitioner. Trepanation has aroused great interest among historians of medicine and religion, anthropologists, archaeologists, and the general public.

Historical Background

In the global context, this author (Sankhyā & Robbins Schug, 2011) presented a glimpse of the

history of trepanation, and more recently Comşa and Sankhyā (2014) elaborated on various types of trepanations and their expansion, techniques, and complications. It is still unknown where the first trepanation was performed. Squier (1863) and Broca (1867) were among the first to draw attention to this practice in Peru. Piggott (1940) thought that it had begun in Europe around 5,000 years ago. In Asia, trepanation is evident from around 4,000 years ago in the Bronze Age of Jericho in Palestine (Giles, 1953; Parry & Starkey, 1936). In Europe, there are good examples of trepanations (Andrushko & Verano, 2008; Bennike, 2003; López, Caro, & Pardiñas, 2011; see Comşa & Sankhyā, 2014 and Erdal and Erdal (2010) for more references) from the Neolithic sites of France and Germany. In Africa, Egyptian skulls show trepanation; the Kabyles, Berbers, Kisii, and Masai are said to still follow trepanation as a medical practice. In Asia, the use of trepanation is known from Afghanistan, the Indian subcontinent, China, southern Siberia, and Japan. It is also known from Oceania in the Polynesian Islands, Bismarck, New Britain, New Ireland, Tahiti, and Melanesia. The North American continent presented a few cases, but most come from South America, especially in the Andean Mountains of Peru, Paracas, Huarochiri and Jauyos, and Cuzco. In Bolivia, trepanation sites date between the fifth and sixth centuries AD.
